In lesions where there is either destruction of the whole lower motor neurone, or degeneration of its axon, fibrillation action potentials can be recorded from the denervated muscle fibres. It is this characteristic change in the electrical activity of the muscle that can be used to distinguish between degenerative lesions of the lower motor neurone and affections in which the integrity of the neurone is preserved although the axon is temporarily incapable of conducting nervous impulses. For instance, in cases of facial paralysis, it has been possible to differentiate, by observing the presence or absence of fibrillation action potentials, between cases of Bell's palsy and those involving more severe damage to the facial nerve. Similarly, in certain cases of sciatica with muscle weakness and wasting, evidence has been obtained that the nerve has been partially destroyed. In such cases, the prognosis is not so favourable as in those in which no fibrillation action potentials can be recorded.

In peripheral nerve lesions, it is not claimed that electromyography should replace tests based on the electrically induced activity of muscles but that electromyography affords a more delicate means of assessing the condition of the motor nerve. It can detect minimal degrees of lower motor neurone denervation and the earliest stages of muscle reinnervation.

In two cases of aphonia, which were diagnosed as being due to idiopathic recurrent laryngeal nerve palsy, the vocal muscles contracted normally, and no fibrillation action potentials were recorded from them. In each of these cases, the affection was found to be due to arthritis of the arytenoid joint.

These investigations have been reported *in extenso* in *Brain* (1944).

The Value of Electromyography in Lesions Involving the Lower Motor Neurone

By RUTH E. M. BOWDEN, M.B., B.S.

DR. WEDDELL and his colleagues, Drs. Feinstein and Pattle, have made clinical electromyography possible and have done much to evaluate the findings in different disorders of the lower motor neurone. Electromyography marks a notable advance in diagnostic methods, and it can now be considered an essential aid to research in these diseases, but it is not equally certain that it is suitable for routine clinical examinations.

to by Mr. Millin is associated with either the indwelling catheter or the line of suture, but is due to incomplete hæmostasis.

The operation of retropubic prostatectomy is not one which should be done by the occasional prostatectomist. We all know of the appalling results associated with transurethral resection when performed by those not competent to do the operation. The same would occur in the operation of retropubic prostatectomy under similar conditions, and much unjustifiable discredit will be brought upon the operation.

Mr. H. P. Winsbury-White: I congratulate Mr. Millin upon his success with a new operation, especially in relation to hæmostasis, which is always a chief concern of every prostatectomist.

I was glad Mr. Millin had mentioned that, following the cystoscopic examination, he was prepared to proceed at once to either transurethral resection or prostatectomy, according to what he found. I, too, feel that this is a wise way to proceed, because there are certain cases in which the decision can only be arrived at by cystoscopy.

I cannot agree that it is not necessary to remove vesical diverticula. If these are left behind then infection of the bladder will remain, whereas one can look forward to a crystal-clear urine in due course for the majority of cases.

The question of post-operative obstruction is a real one with all types of prostatectomy, and I would like to know from Mr. Millin whether it is possible to remove the posterior margin of the prostatic bed by the retropubic route. I, personally, remove this shelf with the diathermy knife and feel that this procedure is an important safeguard.

Mr. Edgar Freshman asked whether Mr. Millin had found it helpful to use a special posterior blade with one of the standard automatic bladder retractors.

Mr. Millin (in reply): I take this opportunity of expressing my gratification at the reception accorded by so many urologists, not only here to-night but in correspondence from many parts of the world, to my retropubic operation. I had been prepared for more opposition. To the President I would say that the "subtle" form of post-operative obstruction he has met with so disastrously indicates no inherent fault of the operation but rather faulty technique—obviously careful inspection and palpation of the prostatic bed had not been carried out.

I do not agree with Mr. Riches that the vertical incision through the capsules is preferable in the case of the grosser enlargements; it may lead to an upward or downward splitting, so jeopardizing either internal or external sphincter. I still prefer the simple preputial stitch for catheter fixation to one traversing the bladder. Unless extensive diathermic coagulation has been employed, cysto-urethroscopy on the eleventh post-operative day shows few if any sloughs, and discharge from hospital on the fourteenth day is safe. I agree with him on the desirability of minimizing the period of indwelling catheter and now aim to remove the tube on the third or fourth post-operative day.

On the question of post-operative spasms, I agree with those who believe that these are primarily due to clots in the bladder and I attribute the freedom from this complication in the operation to the absence of this factor.

To Mr. Winsbury-White I would say that it is simple and frequently desirable to resect a wedge from the posterior lip of the bladder neck in the retropubic approach.

Special instruments are not an essential, but a movable upper blade to the self-retaining retractor is a help.

Using the standardized technique it was the exception to find the return of voluntary contraction before return of excitability to the stimuli of 1/1000 second duration. In the majority of these (all of whom were recovering from complete degenerative nerve lesions) it was possible to make a comparison of the merits of the electrical reactions and the electromyogram (unpublished work). There is conclusive evidence that the electromyogram is superior to the electrical tests in the detection of early reinnervation, and it has the added advantage of being performed more rapidly. Isolated observations by either method are, however, of limited value; the findings on one occasion of a response to a short duration percutaneous stimulus is no proof of innervation, and it is possible to find a feeble and localized contraction with an unusually high threshold to faradism in totally denervated muscle. Where recovery is taking place satisfactorily there is a progressive improvement in excitability. Similarly, the finding of a few motor unit action potentials is no guarantee of functional recovery, it only signifies that some axons have reached the muscle and established functional connexion with muscle fibres. If reinnervation is progressing satisfactorily, there is a corresponding improvement in the number of motor unit action potentials in any particular muscle and, furthermore, the more distal muscles show evidence of reinnervation in anatomical order. The time-lag between the return of motor unit action potentials and voluntary contraction is dependent upon the type of lesion in the nerve (unpublished work).

TREATMENT

Treatment is dependent upon the type of lesion. Degenerative lesions require physiotherapy even if operative intervention is not necessary. In the palsies involving the intrinsic muscles of the hand, it is imperative to prevent atrophy as far as possible. E. C. S. Jackson (1945*a, b*), has shown that the rate of atrophy is rapid in the early days after injury, the volume of the muscles is not restored in the absence of reinnervation. Galvanic stimulation, given in regular and adequate doses, was effective in retarding the early rapid wasting but could not wholly prevent it and, in the later stages, treatment maintained the volume of the hands. In suitable cases (regrettably few) it may be possible to suture the nerve within three weeks of injury, and, therefore, from the point of view of physiotherapy and operative repair, early diagnosis of a degenerative lesion is essential.

At the moment there is no method of determining the state of the nerve at the site of the lesion; it is only possible to diagnose the presence of a complete or partial degenerative or non-degenerative lesion of a nerve. It is always possible to watch the progress of a case, the earliest sign of motor recovery being the appearance of the motor units but this may be undesirable since, if the lesion is a high one, such delay may prejudice recovery should repair be necessary. If a nerve lesion is associated with an open wound on the course of the nerve, or there is a fracture in which there is likelihood of compression or serious damage to the nerve trunk, the findings of a few motor unit action potentials should not be taken as a guarantee of useful function. It may be justifiable to wait for a few weeks, particularly if the lesion is a low one, or associated with injuries where experience shows the prospects are good. However, unless there is reasonably rapid improvement in the number of motor units and evidence of orderly reinnervation of the muscles, exploration should not be delayed. In several instances motor units have been found where only a shred of the nerve trunk remained intact in such cases.

In the light of present knowledge of peripheral nerve injuries, it does not seem possible to abandon any of the available diagnostic methods. The electromyogram is a useful aid to diagnosis, prognosis and treatment. If used in conjunction with information given by the history and full clinical examination, it is possible to make a fairly accurate and comprehensive diagnosis in the majority of cases; but there is still a small group in which the surgeon is faced with the problem, "Is it best to wait and see, or should one look and see without further delay?" Early exploration is indicated if there is any doubt about the ultimate progress of the patient.

In a study of peripheral nerve injuries admitted to the centre under the care of Professor H. J. Seddon, some points have emerged that merit discussion. The problems can be considered under the headings of diagnosis, prognosis and treatment.

DIAGNOSIS

It has been suggested that electromyography has outmoded investigation of electrical reactions of the affected muscles. The results of electrical reactions have been described as unreliable, but the methods used have often lacked uniformity and it is not, therefore, possible to evaluate them adequately. Recently stimulators have been designed by Bauwens (1941), Ritchie (1944), Grey Walter and Ritchie (1945), which enable the clinician to make comparable observations.

In this investigation the stimulator designed by Bauwens has been used. Three durations of stimulus are available, 1/1000, 1/50 and 1 second; the impulses are of square wave form and are delivered at a known constant current which may be selected by the observer. The intensity of the stimulus may be varied independently of duration. A series of patients has been studied using both electromyography and the electrical reactions which were obtained by a standardized technique.

(a) *Degenerative lesions*.—Only 14 cases were seen within thirty-five days of injury, 7 within fourteen days. Using the electrical reactions, conclusive evidence of a degenerative lesion of the nerve was obtained within four to ten days. Nerve conduction distal to the lesion had failed by the third or fourth day, and the reaction of denervation was fully established by the fifteenth day. The earliest fibrillation irritability was seen on the sixth day, and the earliest fibrillation seen was observed on the thirteenth day, more commonly it was not established until after twenty days, in 1 case only after forty-four days. In none was it vigorous before the twentieth day. Motor unit irritability may be found up to about twenty-eight days after injury in the presence of a complete degenerative nerve lesion.

(b) *Non-degenerative lesions*.—*Neurapraxia* (Seddon, 1942): Nerve conduction remains below the lesion, which is in the nature of a block to conduction of impulses. In a man with a lesion that was mainly one of neurapraxia, seen two months after injury, the electrical reactions were comparable with normal, and nerve conduction was present, but there was gross weakness. Electromyography showed a partial lesion, a few motor units and one or two spikes of fibrillation were present. The information given by this alone could not allow of a confident prognosis being given. With the data from both investigations it was possible to give a fairly exact prognosis. In another case of partial axonotmesis and neurapraxia which was seen early after injury, nerve conduction was present eight days after injury, the electrical reactions varied (it is possible that this is not without significance). It was, however, permissible to diagnose the nature of the lesion from these findings, and electromyography provided confirmation. The subsequent progress of the case showed the accuracy of the diagnosis.

(c) *Anomalous innervation*.—This is not uncommon in the hand, it is one of the pitfalls in diagnosis and may lead to serious delay in repair of severed nerves. Electromyography will demonstrate the presence of the innervated and denervated muscle fibres, but cannot give any indication of the origin of the intact nerve fibres. Electrical stimulation of the appropriate nerve trunks can give the necessary information rapidly. An illustrative case may be quoted. An officer had a gunshot wound of the elbow with complete loss of sensibility of ulnar distribution. All the ulnar intrinsic muscles were acting but very weak. Electrical reactions and electromyography indicated a partial degenerative lesion. Ulnar nerve stimulation at the wrist was positive, median nerve stimulation at the wrist was negative for the hypothenar and interosseous muscles. Ulnar nerve stimulation at the elbow above the lesion was negative. At operation a completely severed ulnar nerve was found and sutured, anomalous fibres from the median nerve having entered the ulnar nerve trunk in the forearm. Electrical reactions (which should always include stimulation of the nerve trunks) give evidence of degenerative lesions earlier than electromyography, and they can solve the difficulties of anomalous innervation in a way that cannot be expected of electromyography.

PROGNOSIS

It is generally agreed that electrical reactions are wholly unreliable in prognosis but it is noteworthy that, amongst others, Head and Sherran (1905) and Benisty (1918) reported that in some cases faradic excitability returned before voluntary contractions.

Using the standardized technique it was the exception to find the return of voluntary contraction before return of excitability to the stimuli of 1/1000 second duration. In the majority of these (all of whom were recovering from complete degenerative nerve lesions) it was possible to make a comparison of the merits of the electrical reactions and the electromyogram (unpublished work). There is conclusive evidence that the electromyogram is superior to the electrical tests in the detection of early reinnervation, and it has the added advantage of being performed more rapidly. Isolated observations by either method are, however, of limited value; the findings on one occasion of a response to a short duration percutaneous stimulus is no proof of innervation, and it is possible to find a feeble and localized contraction with an unusually high threshold to faradism in totally denervated muscle. Where recovery is taking place satisfactorily there is a progressive improvement in excitability. Similarly, the finding of a few motor unit action potentials is no guarantee of functional recovery, it only signifies that some axons have reached the muscle and established functional connexion with muscle fibres. If reinnervation is progressing satisfactorily, there is a corresponding improvement in the number of motor unit action potentials in any particular muscle and, furthermore, the more distal muscles show evidence of reinnervation in anatomical order. The time-lag between the return of motor unit action potentials and voluntary contraction is dependent upon the type of lesion in the nerve (unpublished work).

TREATMENT

Treatment is dependent upon the type of lesion. Degenerative lesions require physiotherapy even if operative intervention is not necessary. In the palsies involving the intrinsic muscles of the hand, it is imperative to prevent atrophy as far as possible. E. C. S. Jackson (1945*a*, *b*), has shown that the rate of atrophy is rapid in the early days after injury, the volume of the muscles is not restored in the absence of reinnervation. Galvanic stimulation, given in regular and adequate doses, was effective in retarding the early rapid wasting but could not wholly prevent it and, in the later stages, treatment maintained the volume of the hands. In suitable cases (regrettably few) it may be possible to suture the nerve within three weeks of injury, and, therefore, from the point of view of physiotherapy and operative repair, early diagnosis of a degenerative lesion is essential.

At the moment there is no method of determining the state of the nerve at the site of the lesion; it is only possible to diagnose the presence of a complete or partial degenerative or non-degenerative lesion of a nerve. It is always possible to watch the progress of a case, the earliest sign of motor recovery being the appearance of the motor units but this may be undesirable since, if the lesion is a high one, such delay may prejudice recovery should repair be necessary. If a nerve lesion is associated with an open wound on the course of the nerve, or there is a fracture in which there is likelihood of compression or serious damage to the nerve trunk, the findings of a few motor unit action potentials should not be taken as a guarantee of useful function. It may be justifiable to wait for a few weeks, particularly if the lesion is a low one, or associated with injuries where experience shows the prospects are good. However, unless there is reasonably rapid improvement in the number of motor units and evidence of orderly reinnervation of the muscles, exploration should not be delayed. In several instances motor units have been found where only a shred of the nerve trunk remained intact in such cases.

In the light of present knowledge of peripheral nerve injuries, it does not seem possible to abandon any of the available diagnostic methods. The electromyogram is a useful aid to diagnosis, prognosis and treatment. If used in conjunction with information given by the history and full clinical examination, it is possible to make a fairly accurate and comprehensive diagnosis in the majority of cases; but there is still a small group in which the surgeon is faced with the problem. "Is it best to wait and see, or should one look and see without further delay?" Early exploration is indicated if there is any doubt about the ultimate progress of the patient.

The Detection and Evolution of Adolescent Deformities of the Spine

By F. H. KEMP, M.R.C.P.

IN 1941 Dr. D. Wilson drew my attention to a paper by Shortt and his colleagues (1937) describing dental fluorosis associated with skeletal changes in the inhabitants of certain villages in the Madras Presidency. This aroused my interest in common disorders of the spine as the clinical picture is in many way similar to the type of ankylosing spondylitis (Marie Strümpell) which we see in this country but the radiographic changes are totally unlike. Thus, the first signs of general intoxication begin when the individual is about 30 years old, evidenced by a tingling in the limbs and in the body generally. Pain and stiffness increase until the entire spine, including the cervical region, behaves like a continuous column of bone. There is stiffness of other joints and ossification of the periarticular tissues, tendinous insertions and the interosseous fascia. By the time the condition is fully developed the patient is about 40 years old; there is much cachexia and death ensues from intercurrent disease. There are many minor variations and all cases in a village do not exhibit the same degree of intoxication. The amount of fluorine in the drinking water responsible for these changes was between 3 and 4 parts per million. Similar changes due to fluorine in the drinking water have been reported by Ockersse (1941) in African natives, and by Lyle in China (1946).

The evidence that these changes are really due to fluorine is conclusive. The radiographs show changes exactly similar to those described by Flemming Møller and Gudjonsson (1932) in cryolite workers and by Wilkie (1940) in workers in a Sheffield factory producing aluminium fluoride and hydrofluoric acid. Experimentally, similar changes have been produced by feeding fluorine to animals (Roholm, 1937).

These studies are specially important since they prove that in certain circumstances very profound effects on the skeleton may be excited by substances normally present in food and drink. The quantity of fluorine present in the drinking water necessary to cause these changes is no greater than is found in some waters in some parts of England. Why do we not see these changes in this country?

It seems that the development of the disease is influenced by several factors. Pundit and his colleagues (1940) found that bone changes in fluorosis bore a definite relationship to the economic and nutritional states of the communities. Nowhere in England are the social conditions so unsatisfactory as are those of the native population in the parts of the world where endemic skeletal fluorosis has been described.

In 1942, Dr. Wilson and I published the findings of a similar investigation amongst the inhabitants of Oxfordshire villages. Dental fluorosis, revealed by mottling of the enamel, is very common; there were some very severe cases. We found no evidence of skeletal fluorosis, but there was a remarkable incidence of changes in the spines of the children—of the type described by Scheurmann (1921 and 1936) as "kyphosis dorsalis juvenilis". We continued our investigations (*Lancet*, 1942) and found that these changes were very common. In one school at least a third of the children were affected. We tried to correlate the changes with incidence and severity of the dental fluorosis, but we were unable to prove conclusively that they were related. The worst cases were seen in the lower social classes or in children where there was a history of defective nutrition in the early years. A group of poor Oxford city children (the incidence of dental fluorosis in Oxford city is very low) showed no changes.

The fact which was most surprising was that most of these children had no complaints, yet many were very deformed. As a rule, the changes were confined to the lower six dorsal vertebrae, but in some cases the mid-dorsal region was involved and one or two showed changes in the upper dorsal. There was a variable degree of deformity. Some cases with extremely severe changes had a perfectly normal appearance of the spine clinically, others had a well-marked rounded kyphosis in the affected area. In some cases, only a single vertebra was wedged. It is our view that the presence or absence of deformity is conditioned partly by the natural postural habits of the individual, partly by gravitational influence and partly by the severity of the changes and the degree of softening of the vertebrae.

When we were doing this work, it occurred to me to inquire whether such changes persisted in later life. I had lateral radiographs taken of the chest of a number of medical students and student nurses at the time when they came forward for

(a) Radiograph showing marked irregularities of some of the end-plates and a spur of bone projecting from the anterior surface of the body of D.12.

(b) Second radiograph of the same area taken twelve months later, showing that the progression of the change has reached forward and included the spur of bone shown in the first radiograph.

It is our view that the presence or absence of deformity is conditioned partly by the natural postural habits of the individual, partly by gravitational influence and partly by the severity of the changes and the degree of softening of the vertebrae.

When we were doing this work, it occurred to me to inquire whether such changes persisted in later life. I had lateral radiographs taken of the chest of a number of medical students and student nurses at the time when they came forward for

FIG. 4.

FIG. 4.—Radiograph of the lower dorsal spine of a young woman, aged 38 years, showing wavy outlines of the anterior edges of the vertebral bodies. This is one of the early features of a not uncommon type of osteomalacia.

FIG. 5.

FIG. 5.—Radiograph of a woman aged 67 years, showing only slight deformity and practically normal radiographic appearances; thus proving that structural abnormalities are not the inevitable accompaniment of old age.

The 75 cases of dorsal kyphosis show a variety of radiographic appearances; the kyphosis in some cases was due to wedging of the vertebral bodies, in others to diminution in the disc space, while in some it was due to both. There were other changes which indicated that the group was comprised of cases of mixed aetiology, but the range of appearances at the different age levels was such that one could draw no clear distinction between adolescent and senile cases. Thus, many cases conforming to the description given by Beadle (1931) of senile kyphosis were seen in young adults of both sexes.

The experience I gained from this work forced me to the view that many conditions of the spine which we are accustomed to attribute to old age are really the results of progressive degeneration throughout the years, of malformations acquired in youth. Furthermore, as these changes are so common, they should not be accepted as the cause of a patient's symptoms without a critical examination of all the features of the case. Thus, it is common practice to see patients who have been previously diagnosed as arthritis of the spine on the basis of an X-ray examination, whose subsequent history reveals that they were really suffering from some other complaint.

How are we to classify these patients? I am satisfied with the broad division into those which have functional and those which have structural defects. As a radiologist, I am primarily concerned with the latter group, but I cannot ignore the former since we know that the internal configuration and external shape of a bone change with any constant change in the stress applied; so that it will be best adapted mechanically to resist the stresses placed upon it (Wolff's Law). In the structural group, I feel that we should describe the changes as we see them, in words that do not imply their aetiology. I am opposed to grouping all kinds of different structural conditions under the heading "arthritis deformans", as, for instance, in a recent textbook on orthopaedics, where the title "arthritis deformans" covers a composite picture of a variety of conditions including ankylosing spondylitis. This only leads to confusion.

FIG. 2.—Severe deformity in a young medical student of 19 years, who had no knowledge of his deformity.

FIG. 3.—Medical student aged 19 years. A very unusual compensatory lordosis associated with a simple wedging of the upper dorsal bodies.

their routine chest examinations. These showed a surprising number of changes. Many had irregularities of the end-plates, wedging of the vertebral bodies and quite pronounced deformities. Several young men and women had very marked lipping of the vertebrae, such as one had hitherto associated with advanced old age. I had to question these people very carefully (in order not to raise alarm), but I was able to ascertain that only one of them had any symptoms and this was a young nurse who had, in addition, some scoliosis. Another surprising fact was that they were unaware of the deformities. One young man, aged 19, had a very severe dorsal kyphosis of which he knew nothing. In many cases, the radiographic features of these lesions suggested that they were the healed effects of osteochondrosis of the end-plates (Scheurmann's disease), but others might have been due to long-standing postural errors. These views were confirmed when I was able to do a second examination of some of the children. In some, who had little deformity, the changes had practically disappeared, but others showed changes like the students. (See figs.)

I was also interested to find out how many cases at different age-groups I saw in hospital practice. To answer this question, I reviewed all the radiographs of the dorsal spine which were taken for orthopaedic out-patients for the years 1938/1942 inclusive (Table I, p. 346). I excluded all cases of manifest organic disease such as tuberculosis, secondary neoplastic deposits and ankylosing spondylitis, also cases of gross scoliosis. I tabulated the others according to whether there was a manifest clinical dorsal kyphosis or not. "Normal" was used very liberally to include any case where there was doubt as to the deformity, as well as cases showing irregularities of the end-plates, and marginal lipping which did not have a dorsal kyphosis. From the table it will be seen that our experience is not only limited but selective. It seems very unlikely that the numbers we see are representative of the true incidence of dorsal kyphosis at the different age levels. It will be noticed that the greatest number of patients were seen between the ages of 10 and 40 years, which can only mean that it is customary for the practitioners to pay more attention to complaints of the young people. Notice our very limited experience of the normal.

Arterial Supply of the Mandible

By ALEXANDER MACGREGOR, M.A., M.D., M. and L.D.S. R.C.S.

It is, of course, a common observation that necrosis of large fragments of bone following fracture of the mandible is an uncommon sequela save in the presence of gross comminution and sepsis.

The main arterial supply of the mandible is derived from the inferior dental artery on each side and, according to the older writers, there was little anastomosis across the mid-line of the mandible. The survival of fragments of bone following fracture was in consequence assumed to be entirely due to the arterial supply derived from the numerous muscular attachments to the bone.

Little work has been done to verify the assumption that there was no anastomosis of the two inferior dental arteries across the mid-line: but in 1935 Howkins published the result of his studies in the *Proceedings of the Royal Society of Medicine*. As a result of this work he formed the conclusion that in pigs, monkeys and humans there was little if any anastomosis past the mid-line of the mandible, though it was present in the lips and neighbouring area, probably from anastomosis of the mental and facial arteries.

An opportunity to test this view that no anastomosis of the two inferior dental arteries across the symphysis of the mandible existed, occurred when a patient who had had a fracture in the $\overline{6}$ region died eight days after the injury. The mandible was removed post mortem, stripped of its muscular attachments and, with the aid of a cannula in each of the two inferior dental arteries, a differential arterial injection was performed on each side. Using the ordinary technique, after tying in the cannulae the blood-vessels were well washed out with normal saline. The mandible being held under warm water carmine gelatin in a warm and liquid state was then injected through the cannula into the inferior dental artery of the intact side of the mandible, and trypan blue gelatin was injected into the fractured side. The gelatin was allowed to set, and the mandible split and cut in sagittal section.

It was at once apparent that the trypan blue gelatin extended to the site of fracture in the blood-vessels of the posterior fragment of the left side, and carmine gelatin was present in those of the right side and left side as far back as the site of fracture. It was, therefore, clear that an anastomosis across the mid-line must have been present to allow the carmine gelatin to travel backwards to the fracture area. (A colour photograph of the mandible was taken and this was shown at the Meeting.)

It is not suggested that the muscular attachments of the mandible do not play a most important part in the survival of mandibular fragments following fracture. It is clear that following a bilateral fracture of the mandible with displacement such that both inferior dental arteries must have been severed, the survival of the anterior fragment could not depend upon the inferior dental arteries. It is, however, suggested that this anastomosis of the inferior dental arteries across the mid-line which is present—at any rate eight days after injury—may assist in the survival of parts of the bone, and that the older view that anastomosis across the symphysis does not occur appears, therefore, to be incorrect.

CLASSIFICATION OF DORSAL KYPHOSIS

- (1) Kyphosis without structural changes, i.e. functional.
 - (2) Kyphosis (a) with wedging of the vertebral bodies.
(b) with regular ossification of the end-plates.
(c) with natural disc spaces.
 - (3) Kyphosis (a) with or without wedging of the vertebral bodies.
(b) with general narrowing of the disc spaces.
(c) with regular ossification of the end-plates.
- This may progress so that ultimately there are no disc spaces, resulting in pressure contact between the vertebrae and sclerosis of the architecture of the bodies.
- (4) Kyphosis (a) with or without wedging of the vertebral bodies.
(b) with narrowing of the anterior third of the disc spaces.
(c) with sclerosis of the anterior third of the margins of the end-plates.

This condition may progress until there is calcification in the interior third of the disc and finally bony fusion. (Schmorl's anterior necrosis of the discs.)

- (5) Kyphosis with softening of the vertebral bodies, i.e. osteomalacia.
Type A is characterized by a gradual but progressive wedging of the vertebral bodies and results in a smooth rounded kyphosis.
Type B is seen in older subjects. Characterized by collapse of one or a number of vertebral bodies and decalcification of all the bones.
- (6) Kyphosis associated with osteochondrosis of the end-plates (Scheurmann's disease). This condition is not invariably associated with kyphosis.

Other common associated conditions are:

- (1) *Schmorl's nodes*.—Herniation of the nucleus pulposus into the vertebral body may complicate or aggravate any of the above-mentioned conditions but it is doubtful whether it is a primary causal factor in any of them.
- (2) *Marginal lippling*.—This may be regarded as a reaction to strain.

As a sequel to any of these changes there may be other changes in the spine:

- (1) Changes in the lateral articulations—osteoarthritis.
- (2) Changes in the sacro-iliac joints—osteoarthritis.
- (3) Contact between the spinous processes (usually in the lumbar region on account of the associated lordosis).
- (4) Moulding and elongation of the spinous processes, sometimes, but rarely, associated with local symptoms—a clinical state resembling clay-shoveller's syndrome.
- (5) Changes in the costo-vertebral articulations—osteoarthritis. Often present, rarely severe.

tissue, but under the microscope there cannot be the slightest doubt that the plexus is located within the epithelium.

The rodents in this communication are represented by the rabbit, rat, and mouse. In each of these animals Types I, II, and III were found, and in the rat and rabbit Type IV fibres were also seen. Type II B fibres were particularly conspicuous in the animals of this order. They have a relatively short intra-epithelial course and appear to end in the deeper part of that tissue. They do not have specialized end-organs (Plate I, figs. 8, 9, 10).

In the rabbit Type IV fibres pass out into the superficial part of the epithelium but they do not reach the stratum corneum. These fibres terminate in knob-like swellings (Plate I, fig. 4). It will be observed that the fibres illustrated in this photomicrograph have a wavy intracellular course; in one case this is so marked that the fibre has a distinct loop as the fibre passes towards the periphery.

In the rat the sub-epithelial connective tissue of the gum is particularly well supplied with nerve fibres, which form large nerve plexuses, that cannot be easily divided into deep and superficial plexuses. It is from these that the Type III fibres arise (Plate II, fig. 11).

In the mouse intra-epithelial fibres were found with a peculiar distribution that we have been unable to find in any other animal. On entering the epithelium they bend sharply and run for some distance, parallel to the epithelial-connective tissue boundary, but lie wholly within the former tissue (Plate II, fig. 12).

In this animal (Plate II, fig. 14), we found a definite intra-epithelial anastomosis. A fibre of moderate thickness enters the epithelium and divides into several finer fibres; a second fibre, not shown in this photomicrograph, enters the epithelium a little distance away from the other one and joins with it to form a distinct network. This structure differs from the one described in the mole, earlier in this paper, because in this specimen a definite anastomosis of the fibres occurs. As far as we know, such an intra-epithelial plexus has not been previously described.

In the ferret all five types of intra-epithelial fibres were found, except that II A took the place of II B. Types I to IV resemble those described earlier, and therefore require no further description. The coils were of the V B variety and are shown in Plate II, figs. 15 and 16. From the coils single intra-epithelial fibres arise, which sometimes could be traced to the stratum corneum. In one example the nerve ends with a knob-like swelling, in the other this is absent. We were unable to satisfy ourselves that the bulbous ending was not located within a cell.

In the next portion of this paper, which deals with the innervation of the human gum the description will be extended to include certain intra-papillary endings that have not previously been described. The first of these can be seen in Plate II, figs. 19 and 20. It is situated in the tip of the papilla, and forms an elongated club-like swelling. It occurs at the termination of a thick fibre, which, after a meandering course through the papilla, terminates in this end-organ. The nerve ending is made up of a very distinct neuro-fibrillar network, and gives origin to no intra-epithelial fibres. In its shape it resembles the club-like ending described by Botezat, and photographed by us in the mole (1939a, fig. 3). There is this difference, however; in the mole the end-organ lay within the epithelium. In the camera lucida reconstruction (Plate II, fig. 20) the end-organ is more extensive than in the photomicrograph (Plate II, fig. 19). The reason for this discrepancy is that the end-organ extended to the sections on either side of the one shown in fig. 19, and therefore the complete end-organ can only be seen in the reconstruction which was made from these three sections.

The second of the new intra-papillary structures is illustrated in Plate III, fig. 23. It consists of a single fibre which arises from the nerves of the sub-papillary region. From this region it runs through the papilla and near its apex forms a loop. As it ascends in the papilla it lies close to the epithelium, but at the apex it lies a short distance away from the border of this tissue. In this example, the fibre, as it descends towards the base of the papilla after forming the loop, divides into two fibres, but after a short course these reunite. This division and reunion have not been seen in other loops of a similar nature.

A single example of another type of intra-papillary loops has been seen (Plate III, fig. 24). A number of thick and thin fibres from the sub-papillary space ascend into the papilla; form loops in the tip of this structure, below the epithelium, and then pass backwards on the opposite side of the papilla to run towards the sub-papillary region.

From neither type of loop did intra-epithelial fibres arise. The sections on either side of those containing these structures were carefully examined, and no sign of any such fibres could be found.

To return to the innervation of the epithelium: Kadanoff in 1928 mentions that some human intra-epithelial nerve fibres pass through the tips of the papillæ and arise princi-

A Comparative Study of the Innervation of the Epithelium of the Gum

By W. LEWINSKY, M.D., and D. STEWART, D.Sc., L.R.C.P., M.R.C.S.

From the Department of Anatomy, Victoria University, Manchester

In previous papers we have discussed the innervation of the sub-epithelial tissue of the gum in some of the mammalian orders; and have also given a detailed account of the nerve supply of the epithelium of this tissue in man and the mole. In this paper we propose to describe comparatively the innervation of the epithelium of the gum in sheep, mole, rabbit, rat, mouse, ferret, and man.

The only previous paper on this subject is one by Jurjewa (1913). In it she discusses the innervation of the gum generally without special references to specific animals.

Our material was stained by the modification of Cajal's method devised by Gooding and Stewart (1937). After staining, the specimens were embedded in paraffin and cut into serial sections 12 μ thick.

Examination of the preparations showed that the intra-epithelial nerve fibres varied considerably in their origin from the sub-epithelial nerves, but it was possible for purposes of description to divide these origins into five distinct groups.

These are: Plate I, fig. 1:

Type I: Single fibres arising from bundles in the deeper layers of the connective tissue and running directly into the epithelium.

Type II α : Single fibres arising as in Type I but running for a distance along the epithelial connective tissue border, before they enter the epithelium.

Type II β : Several fibres having an origin and course similar to the single fibres in Type II α .

Type III: Fibres arising from superficial sub-epithelial plexuses.

Type IV: Fibres arising from intra-papillary plexuses.

Type V α : Several fibres arising from large intra-papillary coils situated at the apices of the papillae.

Type V β : Single fibres arising from small close coils also situated at the apices of the papillae.

The intra-epithelial nerves vary in thickness and can be classified as thick and thin fibres. The majority of the fibres fall into the thin group and have a wavy course as they run through the epithelium. The thicker fibres tend to have a much straighter course, frequently taper and sometimes divide as they run towards their termination.

On our examination of the preparations we found that there was a good deal of variation from animal to animal as to the presence or absence of the above-mentioned types of origin. Types I and II, however, were always present.

In the sheep only Types I and II were seen. In this animal the intra-epithelial fibres were all very thin and occasionally divided into two or three branches, but never into a greater number. These fibres end at different levels in the epithelium, which in the sheep is remarkably thick. Some of the fibres have a very long course and can be traced to the stratum corneum. They are usually wavy on account of winding through the intra-cellular spaces. They may either terminate with knob-like swellings, or many end freely without having any specific end-organs. Plate I, fig. 2, shows an example of these fibres.

In the mole Types I, II and III were present, and the greater number of the intra-epithelial fibres belonged to Type I. These varied in calibre from thin to thick. Type II were also frequently seen and they also varied in the thickness of their diameter (Plate I, fig. 3). As a variety of Type I, fibres arose from a leash-like structure in the sub-epithelial tissue, which is characteristic of the mole and has already been described by us and figured in an earlier paper (1939*a*, Plate I, fig. 2).

The intra-epithelial fibres as in other animals either end freely or terminate with knob-like swellings. There is, however, a third type of ending which is very characteristic of the mole, namely the Merkel-Ranvier touch meniscus (Plate I, fig. 6).

In the mole we have found nervous networks within the epithelium an example of which is shown in Plate I, fig. 7. This structure is formed by Type I fibres seen on the right of the photomicrograph, while on the left Type II fibres will be noticed entering one of the epithelial processes and forming a plexus therein. From these II β fibres branches arise, which break up and ramify within the apex of the process. Unfortunately the photomicrograph does not clearly differentiate off the epithelium from the connective

tissue, but under the microscope there cannot be the slightest doubt that the plexus is located within the epithelium.

The rodents in this communication are represented by the rabbit, rat, and mouse. In each of these animals Types I, II, and III were found, and in the rat and rabbit Type IV fibres were also seen. Type II b fibres were particularly conspicuous in the animals of this order. They have a relatively short intra-epithelial course and appear to end in the deeper part of that tissue. They do not have specialized end-organs (Plate I, figs. 8, 9, 10).

In the rabbit Type IV fibres pass out into the superficial part of the epithelium but they do not reach the stratum corneum. These fibres terminate in knob-like swellings (Plate I, fig. 4). It will be observed that the fibres illustrated in this photomicrograph have a wavy intracellular course; in one case this is so marked that the fibre has a distinct loop as the fibre passes towards the periphery.

In the rat the sub-epithelial connective tissue of the gum is particularly well supplied with nerve fibres, which form large nerve plexuses, that cannot be easily divided into deep and superficial plexuses. It is from these that the Type III fibres arise (Plate II, fig. 11).

In the mouse intra-epithelial fibres were found with a peculiar distribution that we have been unable to find in any other animal. On entering the epithelium they bend sharply and run for some distance, parallel to the epithelial-connective tissue boundary, but lie wholly within the former tissue (Plate II, fig. 12).

In this animal (Plate II, fig. 14), we found a definite intra-epithelial anastomosis. A fibre of moderate thickness enters the epithelium and divides into several finer fibres; a second fibre, not shown in this photomicrograph, enters the epithelium a little distance away from the other one and joins with it to form a distinct network. This structure differs from the one described in the mole, earlier in this paper, because in this specimen a definite anastomosis of the fibres occurs. As far as we know, such an intra-epithelial plexus has not been previously described.

In the ferret all five types of intra-epithelial fibres were found, except that II a took the place of II b. Types I to IV resemble those described earlier, and therefore require no further description. The coils were of the V b variety and are shown in Plate II, figs. 15 and 16. From the coils single intra-epithelial fibres arise, which sometimes could be traced to the stratum corneum. In one example the nerve ends with a knob-like swelling, in the other this is absent. We were unable to satisfy ourselves that the bulbous ending was not located within a cell.

In the next portion of this paper, which deals with the innervation of the human gum the description will be extended to include certain intra-papillary endings that have not previously been described. The first of these can be seen in Plate II, figs. 19 and 20. It is situated in the tip of the papilla, and forms an elongated club-like swelling. It occurs at the termination of a thick fibre, which, after a meandering course through the papilla, terminates in this end-organ. The nerve ending is made up of a very distinct neuro-fibrillar network, and gives origin to no intra-epithelial fibres. In its shape it resembles the club-like ending described by Botezat, and photographed by us in the mole (1939a, fig. 3). There is this difference, however; in the mole the end-organ lay within the epithelium. In the camera lucida reconstruction (Plate II, fig. 20) the end-organ is more extensive than in the photomicrograph (Plate II, fig. 19). The reason for this discrepancy is that the end-organ extended to the sections on either side of the one shown in fig. 19, and therefore the complete end-organ can only be seen in the reconstruction which was made from these three sections.

The second of the new intra-papillary structures is illustrated in Plate III, fig. 23. It consists of a single fibre which arises from the nerves of the sub-papillary region. From this region it runs through the papilla and near its apex forms a loop. As it ascends in the papilla it lies close to the epithelium, but at the apex it lies a short distance away from the border of this tissue. In this example, the fibre, as it descends towards the base of the papilla after forming the loop, divides into two fibres, but after a short course these reunite. This division and reunion have not been seen in other loops of a similar nature.

A single example of another type of intra-papillary loops has been seen (Plate III, fig. 24). A number of thick and thin fibres from the sub-papillary space ascend into the papilla: form loops in the tip of this structure, below the epithelium, and then pass backwards on the opposite side of the papilla to run towards the sub-papillary region.

From neither type of loop did intra-epithelial fibres arise. The sections on either side of those containing these structures were carefully examined, and no sign of any such fibres could be found.

To return to the innervation of the epithelium: Kadanoff in 1928 mentions that some human intra-epithelial nerve fibres pass through the tips of the papillae and arise princi-

pally from coils situated in the tips of the papillae. Others take their origin from the loose papillary coils (intra-papillary plexuses), and a third group come from fine networks lying alongside the cells lining the papillae. The first two groups correspond to our Types IV and V, but the third has never been seen by us. In 1938 we described the intra-epithelial fibres belonging to Types II, IV, and V, which were also described by Bradlaw (1939). Since that date we have been able to find all five types of origin in the human gum.

In the photomicrographs accompanying this paper four of the five types are demonstrated. In Plate III, fig. 21, an example of Type I can be seen. Careful examination of the section in which this fibre occurred, and also of the adjoining sections, proved that no intra-papillary coils were present but only the missing intra-papillary part of the fibre; this fibre arose directly from a sub-epithelial nerve bundle, without the intervention of a sub-epithelial plexus. It will be noticed that the fibre terminates with a knob-like swelling in the stratum corneum. In this example the fibre is one of medium thickness, but thin fibres with a similar origin are frequently seen. These latter may enter the epithelium either at the tip or from the sides of the papillae.

Type II_A fibres have been frequently found in the human gum, and a specimen of this type can be seen in Plate II, fig. 17. These fibres arise either from the sub-epithelial nerve or sub-epithelial plexuses. They sometimes divide dichotomously inside the epithelium, and usually have knob-like swellings at their terminations (Plate III, fig. 25). In a former publication we figure an example of Type II_B fibres (1938, Plate II, drawing 2), but at that time its significance was not understood.

In an earlier paper (1939*b*) we noted the presence of superficial and deep sub-epithelial plexuses, but at that time we did not see any intra-epithelial fibres taking origin from these structures. Since then we have observed one example of these Type III fibres in man, and this is shown in Plate III, fig. 22. This photomicrograph demonstrates the presence of a sub-epithelial plexus from which arises one fibre that divides into three branches: The first branch is a long fibre, which runs along the borderline between epithelium and connective tissue, and at no point in its course does it enter the former tissue. The second branch is a Type III fibre, which enters the epithelium; although in this section its intra-epithelial course can only be followed for a short distance, in the adjoining sections its whole intra-epithelial distribution can be made out. Only a small portion of the course of the third branch can be seen; it runs along the border of the epithelium and the connective tissue, and its course resembles that of the first branch.

Type IV fibres have been described and figured in earlier communications (1938, Plate II, fig. 4 and 1939*b*, camera lucida drawing). In these papers, following the example of Kadanoff (1928), the structures we now call intra-papillary plexuses were then termed loose coils. We prefer the name plexus, because these structures form networks occupying the greater part of the papilla, and in no sense of the word can it be said that their fibres become coiled.

We have previously described two types of close coils, which were also seen by Bradlaw. The first was relatively large, and no intra-epithelial fibres arose from it; the second type was smaller, and gave origin to isolated nerve fibres of moderate thickness (Type V_B). We have since met with a third type of coil shown in Plate III, figs. 26 to 30 (Type V_A). This structure is a large loose coil and is not plexiform. It is further differentiated from the intra-papillary plexus by occupying only the upper third or quarter of the papilla. It differs from the coils previously described by being larger and looser, and by having neuro-fibrillar networks in its structure. These networks under lower magnification appear as swellings on the thicker nerve fibres; if, however, these swellings are examined under higher magnification, they are found to consist of fine networks, similar to those seen in Merkel's discs and the nerve ending in Plate II, figs. 19 and 20.

From these coils intra-epithelial fibres arise and can be seen in the reconstruction in Plate III, fig. 30, and also in part in the associated photomicrographs (Plate III, figs. 26 to 29). Two of these fibres were traced for a long distance through the epithelium and ended in the stratum corneum with bulbous swellings. One of these fibres (Plate III, fig. 27) in its course showed a number of varicose swellings, reminiscent of the swellings seen in the very earliest stages of axon cylinder degeneration. The second fibre (Plate III, fig. 29) is interrupted in the peripheral part of its course but can be traced as a dotted line to its termination in the stratum corneum, where it ends in a definite knob. The condition of these two fibres suggests that as the outer layers of the epithelium are shed, at the same time the peripheral portions of the intra-epithelial nerves undergo degeneration and may retain the faculty of forming new end-organs from the non-degenerated part, which then grows outside with the epithelial cells.

In Plate II, fig. 18, a second example of Type V_A can be seen. In a camera lucida reconstruction (not shown) of this and the adjoining sections the coil structure is clearly

brought out. From this coil an intra-epithelial fibre arises and terminates freely in the stratum corneum. Other intra-epithelial fibres, not seen in this photomicrograph, also arise from the coil.

CONCLUSION

Intra-epithelial nerve fibres arise from five sources: In the sheep fibres from only the first two of these sources were found; in the mole and mouse three; in rat and rabbit four; and in ferret and man five.

Intra-epithelial plexuses were observed in the mole and mouse for the first time.

In the human gum three new structures were seen in the papillæ: (1) An elongated club-like swelling containing a neurofibrillar network; (2) simple loops formed either from single or several fibres; (3) large coils containing neuro-fibrillar networks from which intra-epithelial fibres arose.

In sheep, ferret, and man, nerve fibres could be traced to the stratum corneum. In man the appearance of some of the fibres suggested the possibility that the most distal parts of the nerve fibres undergo degeneration simultaneously with the shedding of the surface cells of the epithelium.

EXPLANATION OF PLATES

All figures show photomicrographs with the exception of Pl. I, fig. 1 (drawing); Pl. II, fig. 20, and Pl. III, fig. 30 (camera lucida drawings).

PLATE I

- FIG. 1.—Drawing to illustrate the sources of the intra-epithelial nerve fibres:
 Type I: Individual fibres passing directly from a nerve bundle to the epithelium.
 II A: Individual fibres arising as in I but running along the border between epithelium and connective tissue for some distance before entering the former.
 II B: As in II A, but several fibres running together along the epithelial border, and entering separately into that tissue.
 III: Fibres arising from a sub-epithelial plexus.
 IV: Fibres arising from an intra-papillary plexus.
 V A: Several fibres arising from a large neuro-fibrillar coil.
 V B: Single fibres arising from a small close coil.
- FIG. 2.—Sheep: Intra-epithelial fibres. Note the wavy course of the fibres as they pass between the cells.
- FIG. 3.—Mole: Type II B fibres, some of which divide either before or after entering the epithelium and end freely or with knob-like swellings within the epithelium.
- FIG. 4.—Rabbit: Intra-epithelial fibres; one appears to end within an epithelial cell. There is a very distinct loop on the course of the other fibre.
- FIG. 5.—Mole: Various types of intra-epithelial fibres: (a) thin fibre with long wavy course and free nerve ending; (b) thick fibre ending in a rough elongated swelling; (c) thin fibre with knob-like ending; (d) willow-tree fibres.
- FIG. 6.—Mole: Merkel's discs.
- FIG. 7.—Mole: Intra-epithelial plexus.
- FIG. 8.—Rabbit: Type II B fibres.
- FIG. 9.—Rat: Type II B fibres.
- FIG. 10.—Rat: Higher magnification of epithelial process shown in fig. 9. Note loop-formation.

PLATE II

- FIG. 11.—Rat: Type III fibre with curious acute-angled course.
- FIG. 12.—Mouse: Type III fibre.
- FIG. 13.—Mouse: Type I fibres.
- FIG. 14.—Mouse: Intra-epithelial plexus.
- FIG. 15.—Ferret: Type V. The fibre terminates in a small bulbous swelling.
- FIG. 16.—Ferret: (a) portion of an intra-papillary coil not in focus; (b) intra-epithelial fibre traceable to under-surface of stratum corneum.
- FIG. 17.—Human: Type II A.
- FIG. 18.—Human: Type V A.
- FIG. 19.—Human: Intra-papillary nerve ending located at the apex of the papilla. It is an elongated club-like swelling, containing a neuro-fibrillar network.
- FIG. 20.—Camera lucida reconstruction of section shown in fig. 19 and the two adjacent serial sections.

PLATE III

- FIG. 21.—Human: Type I. The fibre ends in the stratum corneum.
- FIG. 22.—Human: Type III.
- FIG. 23.—Human: Single intra-papillary nerve fibre forming a loop.
- FIG. 24.—Human: Intra-papillary nerve loops.
- FIG. 25.—Human: Intra-epithelial fibre dividing a short distance before its termination into two branches which have bulbous endings.
- FIG. 26.—Human: Type V A. Almost the whole intra-epithelial course of the fibres can be seen.
- FIG. 27.—Higher magnification of fig. 26. One epithelial fibre with a few varicose swellings ends in the stratum corneum with a knob-like swelling.
- FIG. 28.—Human: Section adjacent to the one in fig. 26. At the tip of the papilla fibres containing neuro-fibrillar networks form a part of the intra-papillary coil.
- FIG. 29.—Alteration in focus of fig. 27. The fibre ends with a knob-like swelling within the stratum corneum. Near the stratum corneum the fibre forms a dotted line suggestive of degenerative changes. It is possible that the part of fibre proximal to this degeneration retains the faculty of forming a new ending.

President—T. IZOD BENNETT, M.D., F.R.C.P.

[November 27, 1945]

DISCUSSION ON THE STETHOSCOPE VERSUS X-RAYS

Dr. James Maxwell: The constant advances in medicine are placing an ever-increasing burden on the medical student. The tendency is to continue adding to the number of subjects which he has to study and the detail which he must absorb, and this process is beginning to place an intolerable burden upon his intellectual powers. The time has come when we should consider what must be retained and what may safely be discarded.

In the past the main emphasis in teaching lay on physical examination, and this had hardly altered for a century or more. The methods were those of Laennec and few fresh signs of value were described after his time. The advent of X-rays has added a method of examination which has greatly increased the accuracy of diagnosis. In fact X-rays are now essential in the recognition of all respiratory conditions.

Most doctors are apt to assume and, even worse, to announce to their patients that the failure to detect physical signs implies a healthy respiratory tract. Nothing could be further from the truth. This mistaken idea leads to the unfortunate result that disease of the lungs, and in particular tuberculosis and bronchial carcinoma, is almost certain to be missed at the very stage when treatment would stand a good chance of success.

The reason for this attitude on the part of the doctor must lie in his training. Many months are spent in drilling the student in physical signs, whereas chest radiology is hardly taught in many medical schools. It would appear that the object is to produce a clinician who is competent to reach a diagnosis so long as signs are present, but there is a failure to stress the fact that disease may exist without any abnormal physical findings. Of course it would be difficult to keep the student to the requisite pitch of keenness in the face of such an admission, for he would naturally wonder why he should spend so long learning physical signs when an X-ray must always be taken in order to be sure that something has not been missed. If chest X-rays were entirely reliable there would be something to be said for abandoning the teaching of physical signs, but in fact there is a small but definite percentage of error, even in well-taken films.

The standard postero-anterior film is a composite picture of the whole depth of the chest, and quite large lesions may sometimes fail to appear if they are situated far to the front or to the back. Also, a small lesion may be obscured by a rib or clavicle, and quite a large area of the lung field is hidden behind the heart and below the dome of the diaphragm. Early tuberculosis and early malignant disease may easily be missed, and bronchiectasis may be present without any radiological evidence. Multiple X-rays, which include the standard postero-anterior film and also antero-posterior and lateral views, yield far more information than can be obtained by the method in use at present and they are likely to be increasingly employed in the future. In some cases further evidence will be furnished by a bronchogram or tomogram when no abnormality has been seen on the plain film. In order to be quite certain that the chest is healthy we must therefore still depend upon the combination of physical examination and X-rays; and the teaching of the student must include both of these in their proper proportions.

When one comes to assess the physical signs which are of real value it becomes apparent that most is learnt from the correct interpretation of added sounds. Rhonchi and sibili indicate bronchitis or asthma, while râles reveal bronchiectasis or cavitation, and friction is diagnostic of a dry pleurisy which often leaves no trace on the X-ray. The chief emphasis in the teaching of physical signs should therefore be laid on added sounds. Inspection, palpation and percussion will still have their place, but their message is relatively simple to read and to interpret. Many of the older signs, Grocco's triangle and the rest, are of traditional value only and the time has come for them to be abandoned.

Should the reporting of the X-ray be done entirely by radiologists, or should the student be taught to read his own films? Undoubtedly the clinician, who is familiar with the physical condition of the patient, is in the best position to interpret chest X-rays, and it would seem right that the student should be taught this art at an early stage. This need not necessarily mean an increase on his already overloaded curriculum. His training should start in the departments of anatomy and physiology, where he should receive a thorough grounding in the radiological appearance of the normal chest. Good films, taken in all the standard positions, would be of far more use to him than much of the descriptive anatomy which is taught at present, and normal bronchograms would convey

a clear conception of the bronchial tree as it functions during life. With this basis, and with subsequent instruction in the interpretation of abnormal appearances, the X-ray film would soon convey a message which he would be in a position to understand.

Finally, there is the legal aspect to consider. Failure to advise an X-ray of the chest might be considered to be evidence of neglect in the investigation of a patient. Nowadays it would not be a good defence to show that a full and careful physical examination had been carried out, and this might well be a serious matter for the medical practitioner concerned.

Dr. Peter Kerley: The limits of the stethoscope have been reached but within those limits it is an efficient and indispensable instrument. If a competent physician finds added sounds in the chest it is unusual for radiological examination to be negative provided the proper technique has been used. Moreover auscultation can give decisive evidence of activity in a tuberculous lesion which radiologically appears to be completely healed.

Radiology of the chest is still in its early stages and in the near future we may regard our present standards as obsolete and our pictures as crude images. Most radiological errors are due to inadequate use of the method and reliance on a single film. Although we know that many lesions hidden in the mediastinum can be revealed by a lateral view and that lesions hidden by the ribs and breasts are shown by an antero-posterior view, yet such views are not adopted as routine procedure. Tomography which often throws immense light on unsuspected pathological changes is not used nearly enough.

It is true that many different diseases show what are apparently identical radiological appearances but if we can obtain increased detail and use new methods to delineate all the different structures in the chest, radiological diagnosis may approximate to that of the morbid anatomist. We know that the wave form from a condenser discharge unit is more suitable for chest work than that from a transformer and we know that we can get improved detail by using higher speeds and finer focus tubes. There is no real obstacle to the production of an X-ray set incorporating all these factors. Generally speaking the finest detail on a radiogram is equal in size to the focal spot of the tube. At the moment we are using tubes with focal spots of 1 and 2 mm. but foci of one-tenth of a millimetre capable of withstanding high loads at short speeds should appear during the next few years. The use of these new factors would not only greatly increase detail but would enable us to produce double and quadruple magnification of suspected areas. Some experimental work has already shown that we can differentiate the superficial and deep lymphatics in certain diseases, and we should soon be able to distinguish isolated tubercles from small end-on vessels.

In the examination of the heart X-rays lag far behind the stethoscope but if we consider the cardiovascular system as a whole there are a variety of pulmonary vascular X-ray appearances such as azotemia and impending failure which precede any clinical or stethoscopic findings by an appreciable interval. Cardiovascular radiology has been built up largely by cardiologists who have made great advances by fluoroscopy but screen examination is no substitute for radiography. The use of elaborate equipment and such new methods as angiocardiology should give a new impetus to the investigation of heart disease and might even relegate the stethoscope to a subsidiary position.

Dr. L. G. Blair: As has been shown by the previous speakers, radiology is superior to the examination by the stethoscope, or for that matter, to physical examination generally, in the investigation of the vast majority of chest conditions. In the first place, it is possible to show by X-rays, lesions which give no physical signs, because of the very nature of the lesion or because physical signs are masked by overlying emphysema.

Slides illustrating the very varied conditions in the chest which may give no physical signs were then shown as follows: Primary pulmonary tuberculosis. Early pulmonary tuberculosis. Cavity formation in pulmonary tuberculosis. Miliary tuberculosis. Single cysts. Pneumoconiosis. Secondary carcinoma. Secondary sarcoma. Primary tumour of lung. Hernia. Foreign body in œsophagus.

The speaker then continued

These cases, selected at random, are by no means all the conditions which may present radiologically, and yet show no clinical signs, but they are sufficiently varied to illustrate the very wide field in this group.

Secondly, there is the very large group where physical signs are present, but where, nevertheless, radiology is of considerable importance. It must be remembered that the physical signs found, such as diminished expansion, hyper-resonance or impairment of percussion, alterations in intensity or character of the breath sounds, alteration of voice conduction and the added sounds, merely indicate change in the underlying lung or pleura, such as the presence of fluid or air in the pleural cavity, of consolidation or collapse in the lung, of breaking-down of lung tissue, or of fibrosis; yet these pathological

conditions may be common to many of the diseases found in the chest. There are thus no physical signs of pulmonary tuberculosis, no physical signs of carcinoma, no physical signs of lung abscess, as the textbooks would suggest. The physical signs in all three conditions I have mentioned may be absolutely identical. The shadows caused by these conditions are, however, frequently diagnostic.

Thirdly, and again where physical signs are present, and the diagnosis beyond doubt, in the vast majority of cases the extent of the lesion is more accurately determined by X-ray examination.

To point the contrast of these large groups, and also to be absolutely fair, I would like to mention the comparatively few conditions in which there are physical signs present, and yet no radiological evidence of disease. The biggest group of these are the non-obstructive lesions of the bronchial tree, thus bronchitis may show little or nothing radiologically, and yet the physical signs of the condition may be extensive. There are certain cases of bronchiectasis which will show nothing in the straight X-ray, but the presence of persistent râles, particularly at the base, is suggestive of this condition. On the other hand, silent bronchiectasis may be demonstrated by radiography in the absence of physical signs. Tracheobronchitis, tuberculous or otherwise, frequently gives no radiological evidence of its presence but physical signs of themselves may suggest the diagnosis.

There is another condition where the physical signs are of paramount importance, and that is mediastinal emphysema. Crepitations synchronous with the heart beat, once heard will never be forgotten, and yet this condition as a rule gives no radiological appearances. I think, too, that dry pleurisy shows no evidence of its presence on the X-ray film.

Broadly speaking, in cardiac lesions, physical signs are ahead of X-ray examination, though of course, X-rays can be used to demonstrate alterations in shape and size of the cardiac silhouette. Dry pericarditis is, of course, a purely clinical diagnosis, but in the diagnosis of pericardial effusion, X-ray examination, and particularly screening, is often of supreme importance.

I have shown earlier that X-rays in the vast majority of cases help in the interpretation of abnormal physical signs, but occasionally, physical signs help in the differentiation of an opacity which may be due to fluid or to consolidation. Here, indeed, the physical signs may be of the greatest importance.

The activity or quiescence of a lesion, particularly a tuberculous lesion, is largely a matter for the clinician, from consideration of the history, and possibly physical signs. X-ray examination alone is unreliable.

This group where physical signs may be of paramount importance, is relatively very small. I would suggest, therefore, that in the investigation of chest disease, the present order of examination should be retained, namely, the taking of the history, the physical examination, followed by the X-ray examination. It should be remembered and taught, however, that in the diagnosis and treatment of chest conditions, the history is of supreme importance, radiology comes next, and that the physical signs are frequently only an aid to the correct interpretation of the shadows present on the X-ray film.

[February 19, 1946]

NUTRITIONAL NEUROPATHY IN REPATRIATED PRISONERS OF WAR FROM THE FAR EAST

Dr. C. Astley Clarke and Dr. I. B. Sneddon showed a film, taken at the Royal Naval Hospital, Sydney, illustrating the main clinical features of a nutritional neuropathy which had occurred in repatriated prisoners of war from Hong Kong. The men had been in captivity for over four years and their diet throughout had consisted largely of polished rice, the total nutritive value being only 1,600-1,700 calories daily. In addition the diet had been grossly defective in protein and the vitamin B complex. The neurological signs which developed in various combinations, usually within a few months of captivity, were optic atrophy, macular changes, nerve deafness and ataxia. In general, the ataxia was considered to be due to a peripheral neuritis but in some patients there was evidence of a cord lesion and the picture resembled subacute combined degeneration. One case showed a striking resemblance to amyotrophic lateral sclerosis.

Some patients developed fresh neurological signs while on an adequate parenteral intake of thiamin in the camp hospital. This was part of the evidence which Drs. Clarke and Sneddon brought forward in support of the theory that the neuropathy was not caused by a simple lack of vitamin B complex. In their opinion the syndrome was due to an anti-vitamin or toxic factor present in the rice which inactivated what little thiamin there was in the diet. The thiamin deficiency was rendered more severe owing to the low protein intake which prevented adequate bacterial synthesis in the gut.

The patients had shown little or no recovery since release from captivity in spite of massive vitamin therapy and a high calorie diet. It appears probable that after so long the changes in the nervous system are irreversible.

Dr. E. R. Cullinan: *An outbreak of beriberi in East Africa.*—In rice-eating communities it is usually accepted without question that beriberi results from living on polished rice from which the thiamin content has been removed. Similar outbreaks in various parts of the world among rice-eating communities who have lived on unpolished rice have usually been labelled epidemic dropsy, and thought to have been caused by a toxin. And yet a study of the descriptions of beriberi and epidemic dropsy suggests that the two syndromes are, at least clinically, identical.

The following episode may throw some light on the food aspect of this problem.

In a British garrison in East Africa during the month of March 1945 there was an outbreak among East African troops of a syndrome indistinguishable, except in a few minor and unimportant particulars, from beriberi. Mauritian and British troops in the garrison were unaffected. The syndrome was characterized by oedema of the legs, which was the presenting sign together with right-sided dilatation of the heart and peripheral neuritis. Other monosymptomatic evidence of malnutrition was consistently absent and the general physical state of the patients was good. All men of the garrison were examined by Kekwick, Watts, and myself, and we found 59 cases some of which were investigated in detail. We considered that the rice diet was at fault and on March 24 the diet was almost completely altered. From that time onwards the numbers of cases steadily lessened.

The staple article of food in the normal diet of East African troops is maize meal. In November 1944 it was found that the isolated position of the garrison and the fact that maize meal did not store well under the climatic conditions in the area, precluded the continued use of maize meal as the staple food. Nineteen ounces of rice were therefore substituted for the previous issues of fourteen ounces of maize meal and four ounces of rice. In February 1945 the stock of beans in the garrison was condemned because of high weevil infestation. During the months of January and February 1946 fresh vegetables were in short supply. By the middle of February the diet of the African native troops had thus considerably changed from the normal diet. The European and Mauritian troops were on a different scale. The main differences at this time between the food of the three races were first that the diet of the Mauritians and Europeans was considerably more varied and secondly that rice formed a much greater proportion in the African diet. The rice, which was lightly milled, was stored under good conditions in sacks. It was, however, old, and had on its surface contaminating spores and sporangio-phores of a variety of mucus. This variety of mucus has no known toxic properties to man. In its uncooked state the rice contained a theoretical sufficiency of thiamin and was active and adequate in relation to pigeons. The thiamin estimations were made by Titman.

After examining various possibilities it was found that while fresh lightly milled rice lost only 30% of thiamin in cooking, the suspected rice which was old and contaminated lost over 70%, and, moreover, produced beriberi in pigeons. It is possible that similar outbreaks may exhibit the same aetiological sequence of a toxin acting upon the thiamin and producing an epidemic of beriberi.

REFERENCE

CULLINAN, E. R., KEKWICK, A., WATTS, A. S., and TITMAN, W. L. (In process of publication.)

Dr. J. D. Spillane: I think it might be useful to summarize the clinical features of the nutritional neuropathic syndromes which have been personally observed in prisoners of war of different nationalities during the past few years. It is not possible to provide an aetiological or pathological classification at present but we may discern at least six, fairly distinctive, clinical types of case. (1) Retrobulbar neuritis; (2) Polyneuritis; (3) Ataxic paraplegia; (4) Spastic paraplegia and quadriplegia; (5) Wernicke's encephalopathy; (6) Atypical encephalopathic states.

Other neurological symptoms and signs have been noted—anosmia, ageusia, trigeminal hypoaesthesia, tinnitus and nerve-deafness, nystagmus, diplopia, facial paresis, laryngeal paresis, urgency of micturition and dysaesthesiae of the lower limbs. In a few cases there has been intellectual deterioration.

Retrobulbar neuritis.—This has been common in German and Italian P.O.W.s in the Middle East and in Allied prisoners from the Far East. I have not seen it in German prisoners in this country nor in Allied prisoners from Europe. The condition may be acute or chronic and the eye has not usually suffered other detectable alteration. It appears to be self-limited; vision is rarely worse than 6/60. A few men from the Far East developed acute corneal opacification.

Retrobulbar neuritis may exist alone but it has often been associated with wet or dry beriberi or with the ataxic or spastic forms of paraplegia.

Polyneuritis.—I have not seen polyneuritis in British prisoners from Europe but it was present in some of the German cases from the Channel Isles. It was rare among the Germans and Italians in the Middle East but was very common among Polish refugees from Russia. It was, of course, also very common among prisoners from the Far East among which group the wet and cardiac forms of beriberi and famine oedema occurred.

Ataxic paraplegia.—We first saw this type of disability among the Germans and Italians in the Middle East P.O.W. camps but it has also occurred in Allied prisoners from the Far East. Painful dysaesthesiae of the feet and lower limbs usually preceded disturbance of gait. The latter frequently became grossly defective owing to loss of postural sensibility in the legs. Superficial sensibility was less affected, muscular power was good and the tendon reflexes remained brisk; plantar reflexes were flexor. This type of case was almost always associated with retrobulbar neuritis or some other cranial nerve disturbance.

Spastic paraplegia and quadriplegia.—I have seen this affection only in seven British P.O.W.s from the Far East. There was isolated, but gross, pyramidal disturbance chiefly affecting the lower limbs. The onset was acute, with cerebral signs such as confusion, amnesia, diplopia, loss of vision and generalized rigidity. Those that recovered were left with marked rigidity of the lower limbs, clonus, extensor plantar reflexes and absent abdominal reflexes. There was no sensory loss. I saw a few cases of lathyrism in Syria and but for the history of cerebral disturbance they were identical with these P.O.W. patients. None of the prisoners had apparently eaten any wild herbs or had access to any toxic substance.

Wernicke's encephalopathy.—Only one of the German Middle East cases developed this syndrome and following relief of the stupor and ophthalmoplegia with parenteral thiamin he developed, or more likely was left with, retrobulbar neuritis, deafness and ataxia. Wernicke's syndrome was sometimes seen as a terminal phenomenon in the Polish cases in the Middle East who had polyneuritis aggravated by infective illnesses such as dysentery, typhoid or malaria. I think mild cases of this encephalopathy recovered. I understand they were also seen in Far East P.O.W. camps.

Atypical encephalopathic states.—In a few Italian prisoners with dysentery or typhoid in the Middle East I have seen conditions of stupor, confusion, delirium, even mania, with tetanic spasms of the body, fibrillation, hyperactive tendon reflexes and grasping and sometimes sucking reflexes. The fiery red tongue of nicotinic acid deficiency was not present and in these and somewhat similar cases among Germans from the Channel Isles I have hesitated to call nicotinic acid deficiency encephalopathy. The Germans were suffering from severe diarrhoea and most of them were stained yellow from over-consumption of wild herbs. Many had polyneuritis. I do not think dehydration alone was responsible for these features. Hydration therapy sometimes failed whereas administration of milk, eggs, yeast, liver and vitamin B complex preparations gave satisfactory results.

Ætiology.—I have discussed elsewhere the ætiology of some of these syndromes and suffice it to say here that in none of them has it been clearly shown that they result solely from deficiency of one or more vitamins. The deficiencies which these men suffered were undoubtedly multiple but there is good evidence to suspect lack of some part of the vitamin B complex in the majority of these clinical affections. If such is the case it remains to be seen whether the neurological lesions are a direct result of such deficiency or whether the mechanism is more obscure. I have been impressed by the importance of dysentery and diarrhoea in this respect and we may have to look farther than the vitamins—to disturbance of carbohydrate, fat and protein metabolism and to the essential amino-acids.

But at any rate these observations on the nutritional disorders of malnutrition may focus attention on the metabolic aspects of other obscure disorders of the nervous system which are so common in this country. It is significant that subacute combined degeneration of the spinal cord is one of the few degenerative diseases of the nervous system about which something is known of its ætiology.

Major Brian H. Kirman, R.A.M.C.: I should like to make the following points about those released prisoners who passed through India:

Incidence of psychoses.—There were very few cases of psychosis. Some of the prisoners may at some stage in their captivity have developed Wernicke's encephalopathy and acute confusional states associated with nicotinic acid deficiency as suggested by previous speakers, but if so they had either got better or died before the capitulation of the Japanese forces, since no cases of these syndromes were recognized among patients coming to the hospital town, Jalahalli. The number of psychotics among the population at risk

was no greater than might have been expected had the diet been adequate in all respects. There were no special features about the psychoses which were similar to those encountered in any such group with the same age distribution.

Incidence of pellagra.—There were no cases of pellagra among the psychotics admitted to hospital town and pellagrous features were rare among general medical cases. Neither the mental nor the cutaneous features of pellagra were encountered and a typically pellagrous tongue was exceptional.

Cause of amblyopia.—A number of psychotics who had recovered sufficiently to be able to give a coherent history stated, as did many of the non-psychotic patients, that they had suffered from a sudden attack of amblyopia, in many cases some six months after the beginning of their imprisonment. In many instances it appears that a group of some half-dozen men were affected at the same time. Following the initial, acute attack, frequently with almost complete blindness there appears to have been a tendency to gradual improvement, with or without treatment by vitamin concentrates. In view of this history I would suggest that there is a strong probability that a toxic factor was operative in causing the amblyopia in addition to dietetic deficiency. There are a number of possible sources of such a toxin which could upset the already delicate metabolic balance in these grossly undernourished men. All manner of unusual articles were added to their diet or were smoked in lieu of tobacco. Some which were brought to my notice were, hibiscus, chrysanthemum and mulberry leaves, also cats, snakes, frogs and silkworms. A great variety of wild leaves and fruits were consumed at different times. It is possible that any of these may have contained a toxin which, though relatively harmless to the adequately nourished individual may have been sufficient to have caused amblyopia in the debilitated prisoner of war.

[March 26, 1946]

MEETING HELD AT MIDDLESEX HOSPITAL, LONDON

Disorders of the Sympathetic Nervous System [*Abstract*]

By A. LAPORTE, M.D.

Médecin des Hôpitaux de Paris

DR. LAPORTE took as his subject certain disorders of the sympathetic nervous system, dealing principally with:

- (1) Influence of the sympathetic nervous system in infectious diseases.
- (2) Influence of the sympathetic nervous system on the kidney, particularly in the production of nephritis and in the treatment of suppression of urine.
- (3) The sympathetic nervous system and the treatment of such conditions as angina pectoris, Raynaud's phenomenon, Buerger's disease, œsophageal spasm, &c.
- (4) The technique of choice for the injection of the stellate ganglion and splanchnic nerve.

The first and second sections dealt largely with the experimental work of which much has been due to the inspiration and perseverance of Dr. J. Reilly (and to whom Dr. Laporte held that the greatest credit should be given), Pathologist to the Hôpital Claude Bernard, Paris. In this work Dr. Reilly has had the close collaboration, on the clinical side, of Dr. Laporte during many years. The speaker called attention to a number of startling experiments, such as those in which the intestinal and mesenteric lesions of typhoid can be produced in a very short time by the application of a dilute emulsion of typhoid toxin to the splanchnic nerve, and those in which classical typhoid catatonia can be reproduced in dogs by washing the third ventricle with a very dilute solution of typhoid toxin. Not less interesting were his accounts, illustrated by microscopic sections, showing the effects on the kidneys of nocive stimuli applied to the pharyngeal mucous membrane in animals, effects which fail to appear if the splanchnic nerves have previously been divided.

Dr. Laporte has obtained many favourable results in prolonged angina pectoris, even in cases where the cardiac muscle has been seriously damaged; he has also had many good results in cases of Raynaud's disease, intermittent claudication, and in not a few examples of acute suppression of urine.

He illustrated the technique which has been found most satisfactory and emphasized that, in the case of infiltration of the stellate ganglion with novocain, the technique perfected by Dr. de Seze is so simple that it can be safely and successfully employed by a general practitioner or even a senior student.

The speaker paid tribute to the wonderful work achieved by R. Leriche and his school, and by certain workers in Marseilles.

Section of Laryngology

President—G. EWART MARTIN, F.R.C.S.Ed.

[February 1, 1946]

(1) Squamous-celled Carcinoma of Left Cheek Treated by Operation; (2) Squamous-celled Carcinoma of Left Tonsil.—NORMAN PATTERSON.

The first of these cases was that of a man aged 76. He was seen at London Hospital in 1926 with squamous-celled carcinoma of left cheek previously treated by Mr. Morris on two occasions by diathermy. Operation was carried out on December 29, 1926, by flap method as described by the exhibitor in *British Journal of Surgery* (1937, 25, 330). Recurrence took place in 1943 at old site but also involved the lower jaw. Operation was carried out again by means of flap method, September 3, 1943, at Royal Bucks Hospital. Later bony sequestrum separated. Mr. Patterson showed drawings illustrating the method which he had devised many years ago. He added that the condition was commoner in men than in women, but in his short series there were more women than men (4 men and 6 women).

For the case-history in the second male patient, aged 68, he was indebted to Mr. Robert D. Owen who referred the case to him for treatment. Secondary glands on the affected side were removed at the London Hospital by block dissection in March 1926. Three weeks later diathermy excision of squamous-celled carcinoma of left tonsil, anterior pillar, and base of tongue was carried out.

Both these cases were well, after twenty years.

The President said that formerly dissection was practised in his hospital, but now practically all the cases had been handed over to the radiologist for deep X-rays.

A. J. M. Wright said that in Bristol they were not accustomed to send all these cases to the radiologist. If he himself had a carcinoma in the cheek he would not have the slightest hesitation in choosing somebody to deal with it by diathermy rather than by radiation.

E. D. D. Davis said that it had been his experience that these tumours, treated by means of deep X-rays, died from secondary growths within eighteen months. Personally he preferred diathermy.

Mixed Salivary Gland Tumour in Palate.—R. R. SIMPSON.

F. B., male, aged 38.

September 1945: Swelling right parotid, size of an orange, and swelling of right half of palate, size of a tangerine orange. Palatal swelling bulges forwards and downwards and beyond mid-line causing some difficulty in chewing and swallowing.

Both swellings considered to be part of same tumour and of the mixed salivary type.

Mr. Simpson said that this large tumour had been present for several years. He first saw the patient in 1938, when the tumour was about half its present size. Should the tumour be treated by operation or should it be left entirely alone?

C. P. Wilson said that he did not think there was any doubt but that such cases were malignant. The consensus of opinion was that they were low-grade carcinomata.

If the tumour in the palate was causing trouble there was no reason why it should not be excised. The most satisfactory treatment seemed to be to treat these tumours with radiotherapy and excise them afterwards.

About a year ago he showed a patient in whom a tumour of this type in the peritonsillar region had been excised in 1922. Since that time he had had two or three further tumours in the parotid with recurrences, and had had excision and several courses of radiotherapy. Three years ago he developed a swelling of the ilium, which on exploration was also found to be of the same pathology. The patient was still working after twenty-four years, although he had a facial palsy on the affected side, and would probably show a further recurrence later.

Musgrave Woodman said that the principle which should be followed was to remove these tumours whenever they could be removed. He was certain that they were malignant.

although the malignancy was of low grade. They could be safely removed from the palate. When they occurred in the parotid it was wiser to leave them alone. He thought that they did recede to a certain extent under radium and X-rays. One patient whom he saw was a commercial traveller who had a large tumour which had been under observation for ten years. He did not want an operation because he was afraid that it would damage his voice and so handicap him in his business. He was treated by means of X-rays. He was still alive, but the tumour was rather larger than formerly though it had not increased to any great extent.

E. D. D. Davis said that in his experience X-ray and radium treatment had no beneficial effect on these tumours. It made a subsequent dissection operation much more difficult.

Boeck's Sarcoidosis with Nasal Lesion.—**F. C. W. Capps and J. C. Hogg.**

Male, aged 21. August 1945 attended King George's Hospital, Ilford, with a history of nasal obstruction for eighteen months, swelling of cervical glands, and an intermittent swelling of proximal phalanx of right middle finger. There was nodular infiltration of the nasal mucosa, redness and dryness of the pharynx, and many discrete rubbery glands on both sides of the neck. W.R. and Kahn were negative. W.B.C. 11,400 per c.mm.

X-ray of finger: "Upper half of medullary cavity has lost its outline when compared with other phalanges."

Histology of the nasal lesion: A fibrolympho-angioma was suggested, but the pathologist admitted that he had seen nothing like it before. A section was stained for tubercle bacilli, but none was found.

In December 1945 the patient was seen at St. Bartholomew's Hospital. Clinical picture was substantially the same, but enlarged glands were also found in the left axilla. There was no enlargement of the spleen, and there were no inguinal glands. The radiograph of the chest showed increased hilar shadows suggesting glandular enlargement. Boeck's sarcoidosis was diagnosed. Nodule from nose was inoculated into a guinea-pig, but the guinea-pig unfortunately died of pneumonia the day following. Gland was removed for section and the report was: "Node almost entirely replaced by a mass of pathological tubercles packed closely together. Giant cells are very sparse, but fibrosis is considerable. A few areas of early hyaline degeneration but no caseation. No tubercle bacilli seen."

The histological picture strongly favoured a diagnosis of Boeck's sarcoidosis. The patient was fit and well and there were no other obvious lesions in the upper respiratory tract. The tonsils had been removed.

This was shown as a rare condition of which not many cases were seen. There was some doubt as to the diagnosis at first, but it had been confirmed on histological grounds. There was strong presumptive evidence of sarcoidosis. Mr. Hogg asked for suggestions as to any form of treatment which might improve the condition. The patient had a very poor airway, and it was of this he chiefly complained.

E. D. D. Davis said that clinically this condition looked like a tuberculoma, but Mr. Hogg had told them there was no ulceration. The nodules did not break down and ulcerate. Lupus was a very chronic disease and continued for many years. The section had a different appearance from that found in common lupus.

J. H. Otty said that a number of these cases were seen up North but he looked upon this as a case of tuberculoma of the nasal mucosa and these cases, as a rule, did not ulcerate. He did not think he had seen lupus within the nose without lupus of the cheek or elsewhere in the skin of the face. He had treated them with light diathermy.

Tumour of Nasal Septum (Chondrosarcoma). Operation and Recurrence.—**ROBERT D. OWEN.**

H. J. W., male, aged 43. First seen in September 1943, when he complained of complete nasal obstruction of long standing. Examination showed a red smooth mass arising from the nasal septum and causing complete occlusion of both posterior nares. X-rays showed the right antrum diffusely opaque, with a rounded opacity extending into the left antrum. An exploratory operation was performed, with right lateral rhinotomy approach, and the whole of the nasal septum, with the mass, was removed. The pathological report showed the mass to be composed mainly of chondromatous tissue, but suggestive of chondrosarcoma. In November 1944 another operation was performed for a recurrence involving the floor of the right frontal sinus, extending down to the inner canthus, also in the roof of the mouth in the mid-line. Further sections showed a similar chondromatous structure. It was difficult to judge the malignancy on histological grounds, but the tumour was evidently forming metastases. Opinion varied as to whether any response could be produced by teloradium, and the problem was how far further surgical interference could be carried out. The man's present condition showed further recurrences, particularly in both orbits.

The pathological report showed that two of the sections, namely, those of tissue from the canine fossa and from the left ethmoidal region, consisted mainly of chondromatous tissue. It was difficult to decide from the histological appearance whether it was a simple recurrent chondroma or a chondrosarcoma, but from the way it appeared to be

destroying the tissues it was probably the latter. Another section, probably fibrous tissue from the antrum, showed, in one part of it, some chondromatous infiltration. The tumour was avascular. He asked for suggestions from the Section as to whether surgery was the best line of treatment or whether radiation in one form or another could be introduced.

Gavin Young said that he had at the moment two of these cases. He was assured by the radiotherapist that they were not radio-sensitive, and it had been customary to deal with recurrences as they occurred, by diathermy.

Chondroma.—W. STIRK ADAMS.

A man, aged 22, in September 1933 came under the care of Mr. Holt Diggle at the Christie Hospital, Manchester, suffering from a swelling in the left side of the face, which on surgical exposure proved to be an ossifying chondroma with no evidence of malignancy. The tumour was excised and radium inserted into the cavity of the antrum. From then he remained well until October 1936, when a left orbital swelling occurred, but subsided. This returned in 1938 and, in November, an external operation was carried out for removal of the tumour. Three years later he was referred to Mr. Stirk Adams. At this time there was a firm fullness in his left cheek and inspection of his nasal cavity showed a mass which had extended through the nasal septum and was pressing on the lateral nasal wall on the right side. A sub-labial excision of the mass was undertaken and he remained well until March 1943, when a further operation was carried out because of increasing trismus. The neoplasm had by this time extended posteriorly into the sphenomaxillary fossa. A further partial removal was carried out in the following November, in an attempt to relieve his spasm, and at this time the mass was found to have extended into the basi-occiput and the basi-sphenoid. In April and October 1943, courses of deep X-rays were attempted but could not be tolerated. Biopsy material removed at operations was examined and in every case Professor Haswell Wilson reported a simple chondroma with no evidence of malignancy. The prominent symptom, apart from that of the local lesion was a devastating continuous pain in his face and head, and several of the operations were carried out because, after operation, he obtained relief from this pain for weeks or months. The last attempt to relieve him was carried out in May 1944. He died of increasing weakness but without evidence of somatic secondaries, in November 1944, eleven years after his first symptom.

It was unwise, therefore, to regard any chondroma developing in the nasal capsule as innocent.

Lionel Colledge considered it very unlikely that the tumour was radio-sensitive. He thought it most undesirable to make incisions in the face, they were disfiguring, and they were not necessary from the point of view of obtaining increased exposure. The customary procedure in what was called Rouge's operation gave all the exposure required.

Laryngeal Granuloma following Intratracheal Anæsthesia.—IAN G. ROBIN.

Woman, aged 50. Two years ago she had two gynaecological operations both under an anæsthetic. She complained of hoarseness immediately afterwards and ever since. He brought forward the case rather as a supplement to the Presidential Address (Ewart Martin, *J. Laryng.*, in press). Three months ago there was definite granuloma. He thought there was now a small granuloma on the other side, perhaps due to a recent attack of influenza.

The President said that he had seen three further cases since those previously reported by him. One of these very much resembled the present case. It was difficult to see why a tube passing into the larynx could give rise to a granuloma in one case and not in hundreds of others.

I. Simson Hall said that the number of cases of this form of laryngeal irritation seen was extremely small when the large number of anæsthetics carried out every day in all parts of the country was considered. He suggested that there must be some predisposing cause apart from the trauma of passing the tube. As a possible suggestion of this causation it was noteworthy that fibroma or granuloma of the cord was most liable to form when the voice was used excessively in the presence of slight inflammation. It was possible that slight laryngeal inflammation or slight cold might be a predisposing cause of the granuloma formation following intubation.

C. P. Wilson said that he had seen a case in which a granuloma of the larynx had occurred as a result of an intratracheal tube having been left in the larynx for a week. The nurse in charge of the patient had removed the metal connexion of the tube from the nose without realizing that it was attached to the intratracheal rubber tube. The patient had complained of no discomfort other than loss of voice, and it was not until the surgeon had gone down to the country and examined the patient a week later, that it was discovered that the tube was still in position. In this case the granuloma must have been due to trauma.

J. H. Otty said that he had only seen one such case in Aberdeen in the last fifteen years. He supported Mr. Hall's contention that infection might play a part as the only case in Aberdeen followed a bronchoscopy for bronchiectasis.

R. D. Owen said that he thought the practice of passing the tube down blindly under pentothal anæsthesia only, was to be deprecated.

[March 1, 1946]

DISCUSSION ON IDIOPATHIC RECURRENT LARYNGEAL NERVE PALSIES

Maxwell Ellis: The terms of reference restrict this discussion to about one-quarter to one-third of all cases of recurrent laryngeal nerve paralysis—a figure common to a number of statistical surveys of which the more recent are by New and Childrey (1932), Smith, Lambert and Wallace (1933), Work (1941) and Suchs (1943). The cases represented are drawn from widely different areas in America and Britain, and this agreement in incidence of a disease of unknown aetiology is remarkable and may indicate the constant presence and effect of some unknown, or unsuspected, disease process. The absence of any gross or demonstrable lesion has stimulated speculation. The most popular conception ascribes the condition to an insidious invasive peripheral neuritis secondary to some circulating toxin, or to a vitamin deficiency, or to rapid change in temperature. I fancy that glandular dyscrasia and allergy could be added without fear of contradiction. However, it is fair to mention that Alcantaro and de Ocampo (1939) investigated the larynges of 37 infants suffering from beri-beri and found in 31 cases a partial or complete paralysis of a vocal cord. They believe that irritation of the recurrent laryngeal nerve occurred, followed by degeneration, and dismissed the possibility that pressure on the nerve due to the associated cardiac enlargement might have been responsible. These laryngeal findings are extraordinary, and have been seen recently in returned prisoners of war suffering from nutritional disorders. A few cases occurring during acute infections and after direct exposure of the neck to cold are recorded, but in the bulk of cases no such history is obtainable.

Males are affected nearly twice as frequently as females, and the left cord nearly twice as often as the right. Both cords are involved in only 10% of cases, or even less. The first and second of these observations could lend some support to peripheral neuritis as a cause, since males are more likely to undergo exposure to both weather and infection, and the left recurrent nerve from its greater length is more vulnerable to adjacent disease. But, when all is said, the mere presence in this group of any case proclaims failure in discovering a precursory incident of aetiological significance.

SYMPTOMS

Hoarseness or a weak voice are the usual symptoms for which the patient seeks advice, and choking or coughing attacks may occur on deglutition. Routine post-thyroidectomy laryngoscopic examination has shown that one-third of all cases of unilateral paralysis following the operation are symptomless. It therefore is likely that a number of idiopathic unilateral cases never come for examination and consequently are not recorded. Bilateral paralysis is usually accompanied by dyspnoea on exertion, or even at rest, and sometimes by stridor. This gradation in symptoms of impaired respiratory movements is a function both of the general build and occupation of the patient, and of the relative position of the vocal cords. The former needs no special description, and the latter has probably received overmuch since the paper published by Semon in 1881. The size of the glottic chink is the all-important and vital factor in prognosis.

PROGNOSIS AND TREATMENT

Unilateral paralysis occasionally recovers spontaneously, but in any case the disability is slight, the prognosis therefore good, and treatment unnecessary. Bilateral paralysis seldom undergoes a natural resolution, and it is the chief concern of the practical laryngologist, as fatal asphyxia may at any moment supervene. Prognosis, at the best, is uncertain, and, at the worst, disastrous. These cases are rarely of rapid onset, but they then present no problem as immediate tracheotomy is imperative. When the onset is slower, hasty action is unnecessary, but early decision is desirable if the patient is to return to anything like a normal existence. For many years these cases have been treated by permanent tracheotomy, but such a permanent fistula has certain obvious disadvantages, although when properly constructed low down in the neck and properly managed it need cause only minimal discomfort. However, the patient almost invariably will exert the maximum pressure to rid himself of this disfigurement. Earlier surgical approaches to the problem were first to restore function by nerve anastomosis, and secondly to restore airway by excision of some of the apposed soft tissues. Nerve anastomosis, usually joining the recurrent laryngeal to the descendens hypoglossi, has not proved entirely satisfactory, as in late cases fixation of the crico-arytenoid joint and atrophied muscles are present. Excision of portions of the true and false vocal cords was nearly always followed by the growth of obstructive scar tissue. Following this same principle, Hoover (1932) performed a submucous resection of the vocal cords and soft tissues of the larynx,

hoping to secure adhesion of the mucosa to the internal surface of the thyroid cartilage by firm packing. This procedure has not been altogether successful. Kelly (1941) has introduced a new principle by excising the arytenoid cartilage through a transthyroid approach, hoping (a) that the tension of the vocal cord would disappear, allowing it to fall away from the mid-line, (b) that the respiratory space left posteriorly by removal of the cartilage and atrophy of the cut muscles would be obliterated by scar tissue and remain permanent, and (c) that the position of the anterior third of the cord would be relatively unaltered, preserving a serviceable voice. He has performed this operation on a number of cases and finds that the result is functionally satisfactory. This orthopedic principle was adapted from another introduced by King (1939 and 1940), who began by performing an arthroplasty of the crico-arytenoid joint combined with a tendon transplant (using the anterior belly of the omo-hyoid), and ended by discarding the transplant and creating an arthrodesis of the joint with the arytenoid fixed in abduction and external rotation. The approach is posterior after dividing most of the attachment of the inferior constrictor muscle to the posterior border of the thyroid ala. The posterior crico-arytenoid muscle is divided at its insertion into the base of the muscular process of the arytenoid, the crico-arytenoid joint is opened widely, and the arytenoid freed from the fibres of the interarytenoid muscle along its posterior border and body, and from those of the lateral crico-arytenoid along the anterior border. The vocal process is then encircled by a catgut suture which is drawn through the lamina of the thyroid cartilage and tied so that the arytenoid is fixed in abduction and external rotation. King found by experience that the best result was obtained by operating on only one side, but if there is insufficient airway the other side should be treated likewise. He also found that patients can both open and close the vocal cords, although the larger range of movement develops on the unoperated side. The cord on this side will frequently pass across the mid-line in phonation. He considers that these movements are due to the action of the cricothyroid muscles in increasing the antero-posterior diameter of the larynx, drawing the cords towards the mid-line.

Most of the experience gained in treating bilateral recurrent nerve paralysis has been on cases following injury to the nerve, generally during thyroidectomy, as bilateral idiopathic paralysis is uncommon, but there is no reason why the same principles should not apply. My only personal experience of the Kelly and King operations has been on the cadaver, but the technique is not essentially difficult although one must be prepared to be painstaking in defining anatomical landmarks clearly, and in the precise placing of the anchoring sutures.

SUMMARY

In idiopathic recurrent laryngeal nerve palsies no cause has yet been discovered, but peripheral neuritis is a possibility. Unilateral cases are accompanied by few symptoms, are of reasonably good prognosis, and require no treatment. Bilateral cases are uncommon and always require some form of surgical treatment, of which permanent tracheotomy is the simplest. Recently operations on the arytenoid cartilage and crico-arytenoid joint have been devised, which are rational in conception, not especially formidable in technique, and reasonably successful in outcome.

Macdonald Critchley: Perhaps I can best contribute to the symposium by discussing the phenomenon known as Semon's law and in particular its possible explanation.

In the German edition of Morell Mackenzie's textbook—translated and edited by Felix Semon—we find the following footnote: ". . . in many cases in which central or peripheral lesions unquestionably affect the whole nerve (most frequently in cases of pressure upon the entire trunk of the recurrent laryngeal nerve in cases of aneurysm of the aorta) the symptoms of paralysis of glottis-openers only are seen during life. . . . This proclivity of the fibres going to the abductors to be affected exclusively or long before the others, is very strange."

It was indeed strange and quite unexpected. But Semon had noted it in a series of his own patients and had reported it at the Clinical Society of London in 1878. By 1881 he had been moved to publish in the newly appearing *Archives of Laryngology*, a paper—now a classic—under the elaborate title "Clinical remarks on the proclivity of the abductor fibres of the recurrent laryngeal nerve, to become affected sooner than the

adductor fibres, or even exclusively, in cases of undoubted central or peripheral injury or disease of the roots or trunks of the pneumogastric, spinal accessory, or recurrent nerves".

But unfortunately he had been forestalled a few months before by Rosenbach, who upon the basis of a solitary case of carcinoma of the œsophagus had stated "... in compression of the trunk of the recurrent, the function of the abductors suffers first, and that of the adductors is implicated only later on".

The eponymous term Semon's Law has rightly passed into medical terminology, though some Continental sticklers may continue to speak of the Rosenbach-Semon law, or even the Gerhardt-Rosenbach-Semon law.

With the passage of sixty years it is not surprising that cases should occasionally be reported which show themselves (or appear to) as exceptions to this law. Perhaps it is a matter for wonder that the exceptions have been so few. But for this reason some—like the Chevalier Jacksons—would prefer to speak of Semon's rule rather than Semon's law, a distinction which might be regarded as a quibble.

Perhaps the majority of those exceptions comprise pseudobulbar laryngeal palsies, due to supranuclear lesions. This at least is what Semon afterwards affirmed, namely in 1913, when he emphasized that his law only concerned the laryngeal nerves from the nucleus downwards. Semon must, however, bear some of the blame for this misconception, for all his early papers on the subject referred to both peripheral and central lesions. By "central" Semon probably meant "nuclear" lesions, though most present-day neurologists might well assume these to refer to supranuclear locations.

Anyway the point is a good one, and the fact remains, I think, that supranuclear affections of the nucleus ambiguous do not necessarily behave according to Semon's law, e.g. in cases of pseudobulbar and progressive spastic bulbar paralysis, as shown by Collier, Critchley and Kubik, and others.

Later authors have read more into the law than Semon originally stated in that it is now taught that with progressive affections of the recurrent laryngeal nerve, the abductors are the first to be affected, while the tensors of the cords are implicated later, and the adductors last of all. Or, in terms of the muscles involved, the crico-arytenoideus posticus suffers first, then the thyro-arytenoideus, and lastly the crico-arytenoideus lateralis. The arytenoideus, having a bilateral nerve supply, is not affected in unilateral cases, while in bilateral disease it is affected very late.

Experimental physiologists have since shown that the law holds true for processes other than pressure effects or disease. Thus the abductor components of the recurrent laryngeal nerve have proved to be more sensitive than the adductor elements to such influences as drying (Risien Russell) and to freezing (Gad and Fränkel).

The many and diverse views that have at various times been proposed to explain Semon's law may best be arranged in chronological order.

Muscular hypotheses.—(a) Abductor group requires a greater volume of blood (Clausberg). (b) Abductors differ in chronaxy from the adductors (Tarneaud). (c) Abductors early lose their excitability after death (Jeanselme and Lermoyez). (d) Adductors are mechanically better placed than the abductors (Gowers). (e) Abductors suffer because the nutrient artery is involved (Robinson).

Location of abductor fibres within the recurrens.—A more peripheral siting of the abductor fibres suggested (M. Mackenzie)

Double innervation of adductor group.—(a) From spinal components (Tissier). (b) From superior laryngeal nerve (Cohen Tervaert).

Abductor paresis is really an irritative adductor spasm or adductor contracture (Krause). *Glottis-closure is subserved by a powerful cortical centre* (Bosworth; Risien Russell; Horsley).

Abductor proclivity is an instance of a general axiom that extensors are more vulnerable than flexors (Ferrier).

Glottis-closure is phylogenetically an older function of the larynx than is the opening of the glottis (Negus).

Some of the foregoing suggestions can be disposed of quickly.

Morell Mackenzie's original idea was that the abductor fibres were disposed peripherally in the recurrens and were therefore sensitive to pressure. But Risien Russell later showed that the abductor filaments lie mesially and the adductor filaments laterally.

The theory of double innervation is a plausible one but is not supported by anatomy, though bilateral innervation of the arytenoideus is of course a factor which may assist in maintaining closure of the glottis in unilateral lesions of the larynx. The fact that Semon's law applies to lesions of the vagus as well as the recurrent, and its occurrence in bilateral lesions of the larynx, are points against the theory of double (or bilateral) innervation.

Spasm of adduction (rather than weakness of abduction) is a not unnatural suggestion, and was at one time entertained by Semon himself. But subsequent experience rendered this idea unlikely, (1) because the adductive process was observed at times to continue for years—far longer than nerve-irritation was likely; and (2) because dissection of the laryngeal muscles confirmed a greater degeneration in the abductor set. Krause's theory of primary neuropathic contracture of the adductor muscles was the basis of another prolonged controversy, and here again Semon was able to point out that when laryngeal palsies accompanied multiple palsies elsewhere in the body, loss of power, and not contracture, was the rule.

The role of the cortex was regarded as a possible explanation, and, supported by most careful experimental work by Risien Russell, Horsley and Semon himself, has never been really put out of court. It ties up with the older conception of the dual role of the larynx, the adductive elements being connected with phonation and the abductive elements with respiration. The former was found to have considerable representation in the cerebral cortex, the latter having mainly a medullary hierarchy—though the circumstances differed slightly according to the kind and age of the animal studied.

Much attention has been paid to the idea that Semon's law is merely part of what might be called Ferrier's law, which states that in neurological disease the extensors of the limbs are always affected more than the flexors. It was imagined that the limb-extensors correspond with the laryngeal abductors, and the flexors with the adductors. Semon, however, pointed out that to invoke a general law of extensor vulnerability was merely to re-state the problem and simply to postpone the explanation. (Indeed the correctness of Ferrier's law is open today to serious doubt.) Semon made the point that both flexor and extensors of, say, the lower limb subserve the same functions of posture and of progression, while the adductors and abductors of the larynx serve two separate and distinct functions, namely phonation and respiration. Secondly abductor palsy is characteristic of organic disease and adductor palsy of hysteria; whereas no such selectivity occurs between functional and organic paralysis of a limb. Lastly Risien Russell had found that after division of the adductor filaments of both recurrences, stimulation of the cortex would not produce any inhibition of the abductors, such as would be expected to occur in the case of true antagonistic muscles.

The brilliant researches of Negus have afforded what is so far the most satisfying solution to the problem of Semon's law. Far from subserving two functions as Semon taught, the larynx according to Negus, has several, of which the most primitive is that of shutting-off the air passages from the gullet. For this purpose a sphincteric muscle at the entry of the larynx was developed, the homologue of the adductor group. Both phylogenetically an ontogenetically the glottis-closers are the oldest structures in the larynx and presumably therefore are more resistant than structures of later appearance and development.

Today this is perhaps the most plausible way of accounting for Semon's law, though one must admit that as an hypothesis it is not completely satisfying. The sphincteric conception of the larynx is perhaps an over-simplification. Most sphincters—if not all—are endowed with a sympathetic as well as parasympathetic innervation, which is not the case in the larynx. Furthermore, the interpolation of the arytenoid cartilages, and the division of the larynx into upper and lower compartments detract from the idea of a simple valve-like or sphincteric action.

Nevertheless it is not unfair to regard the larynx as being made up of muscular structures of different ages, functions, and degrees of vulnerability. Hence we are really back again in 1913 when Semon himself could only conclude that the earliest destruction of the abductors in progressive lesions implies that there exists an actual difference in the biological composition of the laryngeal muscles.

Perhaps a study of phonetics might throw some light upon the problem. The appearance of the so-called "glottal stop" is an early but important landmark in the development of infant speech and is mediated by structures which exclude food from the air passages. Their ancillary influence upon phonation is to evoke the guttural sound [k] (unvoiced) and more especially the voiced guttural sound [g]. The vocalization of newly born babies is chiefly made up of vowel sounds. Consonantal sounds appear later. Although more data are required, it is possible—if not probable—that the voiced and unvoiced gutturals are among the earliest of the consonantal cries and appear within the first month. We believe that in early infancy, vocalization denotes discomfort, and silence means satisfaction. But at a little later date the infant becomes capable of emitting comfort noises. These are symbolized by consonantal sounds of later appearance. In other words the earliest consonantal sounds are mediated by the glottal stop, i.e. the adductor elements, and connote discomfort. The wide range of abductor sounds associated with comfort appear later.

adductor fibres, or even exclusively, in cases of undoubted central or peripheral injury or disease of the roots or trunks of the pneumogastric, spinal accessory, or recurrent nerves".

But unfortunately he had been forestalled a few months before by Rosenbach, who upon the basis of a solitary case of carcinoma of the œsophagus had stated "... in compression of the trunk of the recurrent, the function of the abductors suffers first, and that of the adductors is implicated only later on".

The eponymous term Semon's Law has rightly passed into medical terminology, though some Continental sticklers may continue to speak of the Rosenbach-Semon law, or even the Gerhardt-Rosenbach-Semon law.

With the passage of sixty years it is not surprising that cases should occasionally be reported which show themselves (or appear to) as exceptions to this law. Perhaps it is a matter for wonder that the exceptions have been so few. But for this reason some—like the Chevalier Jacksons—would prefer to speak of Semon's rule rather than Semon's law, a distinction which might be regarded as a quibble.

Perhaps the majority of those exceptions comprise pseudobulbar laryngeal palsies, due to supranuclear lesions. This at least is what Semon afterwards affirmed, namely in 1913, when he emphasized that his law only concerned the laryngeal nerves from the nucleus downwards. Semon must, however, bear some of the blame for this misconception, for all his early papers on the subject referred to both peripheral and central lesions. By "central" Semon probably meant "nuclear" lesions, though most present-day neurologists might well assume these to refer to supranuclear locations.

Anyway the point is a good one, and the fact remains, I think, that supranuclear affections of the nucleus ambiguous do not necessarily behave according to Semon's law, e.g. in cases of pseudobulbar and progressive spastic bulbar paralysis, as shown by Collier, Critchley and Kubik, and others.

Muscular hypotheses.—(a) Abductor group requires a greater volume of blood (Clausberg). (b) Abductors differ in chronaxy from the adductors (Tarneaud). (c) Abductors early lose their excitability after death (Jeanselme and Lermoyez). (d) Adductors are mechanically better placed than the abductors (Gowers). (e) Abductors suffer because the nutrient artery is involved (Robinson).

Location of abductor fibres within the recurrens.—A more peripheral siting of the abductor fibres suggested (M. Mackenzie).

Double innervation of abductor group.—(a) From spinal components (Tissier). (b) From superior laryngeal nerve (Cohen Tervaert).

Abductor paresis is really an irritative adductor spasm or adductor contracture (Krause). *Glottis-closure is subserved by a powerful cortical centre* (Bosworth; Risien Russell; Horsley).

Abductor proclivity is an instance of a general axiom that extensors are more vulnerable than flexors (Ferrier).

Glottis-closure is phylogenetically an older function of the larynx than is the opening of the glottis (Negus).

Some of the foregoing suggestions can be disposed of quickly.

Morell Mackenzie's original idea was that the abductor fibres were disposed peripherally in the recurrens and were therefore sensitive to pressure. But Risien Russell later showed that the abductor filaments lie mesially and the adductor filaments laterally.

The theory of double innervation is a plausible one but is not supported by anatomy, though bilateral innervation of the arytenoideus is of course a factor which may assist in maintaining closure of the glottis in unilateral lesions of the larynx. The fact that Semon's law applies to lesions of the vagus as well as the recurrent, and its occurrence in bilateral lesions of the larynx, are points against the theory of double (or bilateral) innervation.

in a state of very restricted activity, but he had not seen her for a long time. The other one was the case to which Mr. Davis referred. He thought for a time the phrenic-recurrent union had succeeded, but he had lost sight of her, and it was evidently a failure. Therefore only 1 of the 5 cases from a surgical point of view was successful. Unless the paralysis was of very short duration it was unlikely that a surgical success would be attained.

When he reported these results in 1939 he suggested that from a practical surgical point of view they might get all they wanted in relieving the patient's respiratory obstruction by fixing one of the cords in an abducted position. The operation he then suggested was to expose the arytenoid cartilage, abduct the vocal process, and fix it in the abducted position. In order to do that an incision was made down to the pyriform fossa by retracting the ribbon muscles forward and incising the inferior constrictor along the posterior edge of the thyroid ala. It was possible thus to expose quite easily from the outside, without opening the pharynx, the crico-arytenoid joint, which was opened and the arytenoid was exposed. The posterior edge of the ala should be excised.

The difficult part was to drill a hole in the arytenoid cartilage in which a suture was put near the vocal process to draw the vocal process out. The arytenoid cartilage was fixed in abduction by drilling two holes in the thyroid ala through which the ends were passed and tied outside the ala. Mr. Archer gave him the opportunity of doing that by sending to him from Manchester in 1942 a woman aged 40 who had compensated mitral stenosis and had had a thyroid operation, and eighteen months later a tracheotomy on account of double abductor paralysis causing stridor and distress. He carried out the operation described, and within a few days the tracheotomy tube was withdrawn and she breathed comfortably. She had written later stating that she was quite comfortable and had a good voice.

It was important that nothing should be done to disturb the intact laryngeal mucosa, and that was why all the operations devised for excising the cord were failures; one simply replaced the paralysed cord by a fixed scar. He had one patient, a woman from the North of England, who had a palsy with a tracheotomy, and she proved to be a person with acromegaly. In carrying out the operation the arytenoid cartilage became dislocated and he removed it altogether and fixed the cord, as he hoped, in an abducted position. In that case the relief was short-lived; she did get rid of the tracheotomy tube, but it had soon to be replaced. But on the basis of the first case the first method seemed to him quite a practicable one.

— (1929) *British Encyclopædia of Medical Practice, Surveys and Abstracts*, p. 12. London.

Gavin Livingstone recommended the clinical use of the electromyograph as an aid to diagnosis. A long bipolar needle was inserted through a laryngoscope under local anæsthesia into the adductor and abductor group of muscles and the nerve impulses reaching the muscles were recorded.

In one case of apparently complete paralysis of the cord, the myograph showed normal nerve impulses coming through, but no movement was seen—the condition not being due to a nerve lesion.

There was no real technical difficulty in the needling, but the electrical recording and cathode ray amplification needed expert supervision.

T. B. Layton said that he liked the term "idiopathic" better than "paralysis of unknown origin". He wondered whether there were such things as idiopathic paralyses of the larynx and would suggest that all these cases called idiopathic were really cases of fixed joints. An arthritis of the joint caused the cord to be fixed during the acute stage, from which it recovered. He had seen one such case in a young doctor who had been told by another medical man that he had an idiopathic paralysis of the cord. This patient had been spending a winter holiday in Switzerland, and after playing in hot sunshine he was seized with a chill as the sun went down behind the mountains and he felt a severe pain in his neck and a sensation of frightful coldness. From that moment he became hoarse. The speaker suggested to him that what was wrong was a fixed joint, not a paralysis of the cord, and that it might come right, and so it proved. A case of undoubted paralysis of the cord was certainly a serious, and probably a grave, lesion.

Lionel Colledge, in reply to a question as to what sort of voice these people had after operation, said that in the woman whose case he had described the voice was a little rough but strong. Generally the patients with palsies had normal voices after a certain time for adaptation. They adapted themselves to talking with one cord, and the voice, perhaps with a little speech therapy, became normal.

J. Angell James described the case of a soldier who had been wounded by a mortar bomb, a fragment of which had entered his neck through the right posterior triangle.

Much more work is required along these lines but already it seems as though phonetics might produce a confirmatory piece of evidence and serve to bring Semon and Negus still further into line.

E. D. D. Davis: The term "idiopathic" means without pathology and without cause. Paralysis of the laryngeal nerve of unknown or obscure origin is what is really meant. Paralysis of the left or right recurrent laryngeal nerve is common in pulmonary tuberculosis, caused by enlargement of the mediastinal glands. The tuberculous lesion may heal and the paralysis may disappear or remain. Similarly cases of syphilis causing double abductor paralysis recover with treatment and in both diseases the original cause of the paralysis may be obscure. Paralysis of the laryngeal nerve occurs in thrombosis of the posterior inferior cerebellar artery and this paralysis sometimes remains after all the other symptoms have disappeared. Bilateral or unilateral abductor paralysis arising from enlarged mediastinal glands has occurred on very rare occasions in children. Such cases of laryngeal obstruction have been admitted to the Fever Hospital for suspected diphtheria and a tracheotomy has been necessary. Mr. Ridout showed a post-mortem specimen of such a case at this Section many years ago. Enlarged mediastinal glands had stretched the nerves.

The enlarged glands are not always easily recognized by X-ray photographs and these cases may be described as of obscure origin. I have seen 5 cases of double abductor paralysis following thyroidectomy which I have kept under observation for some years.

The first case developed double abductor paralysis a short time after the operation. This woman had a tracheotomy performed and was more or less an invalid all her life and did not attempt to go to any social function. The next case, a young woman of 22, kept her household awake at night with her noisy stridor. She was embarrassed on exertion and had attacks of dyspnoea. She married and when she was pregnant it became necessary to terminate the pregnancy owing to the difficulty in breathing. The right phrenic nerve was united to the right recurrent laryngeal nerve and when seen a few years later there was no movement of the right cord. The patient thought she was better but there was no alteration in the abductor paralysis. This patient has attacks of bronchitis of the base of the right lung with retention of secretion. These cases after some years show relaxation of the adductor muscles and particularly the interarytenoides or transverse muscle. The larynx shows an elliptical chink between the anterior two-thirds of the vocal cords, and a larger triangular area between the arytenoids, making almost normal respiration possible. The question is, can the patient wait for this happy result without a catastrophe?

If tracheotomy is performed it should be a low one and a tracheotomy tube would have to be worn for many years.

Double abductor paralysis of syringobulbia is not always complete and occasionally there is slight movement of one or both cords and also the adduction of the cords is not so marked.

Lionel Colledge said that he had been interested for a long time in the question whether it was possible to restore movement to a paralysed cord. It was not of much consequence where the paralysis was unilateral, because that only very exceptionally produced any respiratory difficulty. Attempts were made by Ballance and himself in 1925 to discover whether by any form of nerve anastomosis movement could be restored to one or other side. Most of the nerves of the neck were tried, including the descendens noni which had been mentioned. No good result was obtained with the descendens, but satisfactory results were claimed in America. When the recurrent was divided either the cord might remain in its previous position, median or paramedian, or it might be moved out, depending on the length of time of the paralysis and the degree of contracture of the muscles. If the contracture was firmly fixed at any one position the cord would not move out. That was all that happened with the descendens.

They tried on monkeys the effect of using the phrenic, which seemed more promising, because respiratory impulses were going down the phrenic, and therefore there was more hope of restoring respiratory movement to the cord. Experimentally it worked very well in animals. In one case it was possible to show a monkey with both cords moving quite freely on the phrenics. Therefore he tried operation on the human being on this experimental basis. He had carried it out on 5 patients. In 2 nothing happened at all. One was a woman with a bilateral recurrent paralysis following thyroid operation, and there was no result. In another there was the same thing, and in both these cases a tracheotomy was done. The third case was a man with what Mr. Davis would call paralysis of unknown origin. The cord moved out (in the other 2 it did not move at all), but he got an infection of the arm about six weeks later to which he succumbed.

The other 2 cases were both in young women. One, he felt sure, succeeded quite well because the patient was able to dance and lead quite an active life after being

JOINT DISCUSSION No. 1

Section of Orthopædics with Section of Surgery

Chairman—W. B. FOLEY, F.R.C.S.

(President of the Section of Orthopædics)

[February 5, 1946]

TREATMENT OF ACUTE OSTEOMYELITIS WITH PENICILLIN

R. Vaughan Hudson: Since March 1943 we have submitted to laboratory and clinical investigation 400 cases of penicillin-sensitive infections at various sites in the body. 37 of these cases happened, or proved to be, acute or subacute osteomyelitis.

In 30 cases the organism causing the infection was the *Staphylococcus aureus* and in 7 *Streptococcus pyogenes*. In the majority the infection had been present for some days, in only two was the disease seen as early as the fourth day, and in one case it was a hundred and fifty days before we received the patient. The youngest patient was 1 year old and the oldest 70 years of age.

It must be agreed that osteomyelitis is one of the most tragic of diseases which can affect the children of any nation, and it is also surprising the number of adults who are primary sufferers from this disease.

There are certain points about the causation of osteomyelitis which are perhaps not well known. First the history given by the patients or their relatives is often misleading; with deliberate questioning it is found that the initial cause of the illness, a carbuncle, boil, or respiratory infection, has been forgotten and healed three to four weeks before the identical organism produced the train of symptoms known as acute osteomyelitis.

Second a persistent septicæmia of an apparently unknown origin is more likely than not to be due to an osteomyelitis, and, alternatively, if a septicæmia is permitted to persist it will more probably than not give rise to an osteomyelitis. In 6 of our cases, had penicillin not saved the life of the patient and given time and opportunity for the feeding focus to be discovered in one of the bones, the patient would have died with the cause of his malady unrecognized, for it is not usual for every bone in the body to be examined in the post-mortem room by the pathologist.

We have not received for treatment cases of established acute traumatic osteomyelitis such as have been seen by many who have worked in the Field. Accidental trauma, however, has undoubtedly focalized the site of infection to a bone in patients who were carriers of an active organism. Surgical trauma by the dissemination of infection, for example the surgery of infected accessory air sinuses, soft tissue infections, and even such a trivial operation as the removal of a nail for paronychia, has been the immediate or delayed cause of 20% of all our cases.

The right vocal cord was completely paralysed, and a skiagram showed a fragment measuring 4 mm. by 2 mm. in the neighbourhood of the right transverse process of the sixth cervical vertebra. He had considerable discomfort in the neck and surgical intervention was thought justifiable. The carotid sheath was exposed and the fragment found embedded in the medial half of the vagus nerve. The fragment was removed and the sheath repaired, and it was hoped that there might be regeneration of the nerve and recovery of the vocal cord. A year later he wrote that his voice had completely recovered, but only two days ago the man came to be seen, and the cord was still paralysed.

The President said the discussion had proved extremely interesting. Cases of bilateral laryngeal paresis were, fortunately, very uncommon. Unilateral paresis rarely gave trouble apart from loss of voice for a short period. The voice cleared when the other cord compensated but the paresis usually remained complete. He had in mind two ministers, both of whom have unilateral vocal cord paresis, and yet they have apparently normal voices. They were both voiceless for a short period only. In one case of sudden onset of bilateral paresis an urgent tracheotomy had to be performed and the patient (who was a jeweller) made his own tracheotomy tube with a small valve across the mouth controlled by a fine "bowden" wire so that he could speak normally without closing the tube with the finger.

Following on the publication of Dr. Irwin Moore's paper in 1923 (*Jnl. Laryn. & Oto.*, 38, 236) he (the President) had tried the anterior operation. One case was almost successful but he split the cartilage in the middle line and by some mischance one cord was replaced rather below the other. The result was quite good except that the voice was what might be called a forced whisper only.

He had tried grafting the anterior end of the cords but without success although one case gave quite good results for about a year. He had only tried the posterior route once and although the result seemed quite good the patient had a lot of stridor and thought he was better with the tracheotomy tube.

The President agreed with Mr. Layton that some of these so-called idiopathic pareses were really joint infections.

Maxwell Ellis, in reply, agreed that "idiopathic" was not a satisfactory term, but at least they knew what it meant. It was very interesting that Mr. Colledge in 1939 should have embarked on the precise procedure that King described in the same year with a report of 24 cases. King did not bore a hole through the vocal process, because that was a difficult procedure technically. It caused fracture and was not easy to carry out. He ran the suture round the inner side of the vocal process and then did precisely what Mr. Colledge had described. The point was not to enter the larynx; if one did scar tissue formed. The second case which Mr. Colledge described followed the technique which Kelly employed in America.

Some speakers had suggested that recovery was an instance of functional, not anatomical, cure. Undoubtedly a number of these unilateral cases did resolve and the cord returned to normal.

If Mr. Layton had put his question before Mr. Livingstone had spoken he would not have known how to answer it, but Mr. Livingstone had described an electro-myographic method of detecting the response of a nerve, and that might distinguish between cord paralysis and joint fixation. Without being too scientific and dogmatic he felt sure Mr. Layton would agree that on the basis of clinical experience, while there were a number of things not very easy to describe or define, one might be quite sure that one was dealing with a particular condition, generally on the basis of repeated examinations at different times.

The whole point of the Kelly operation of removing the arytenoid was to give a good airway posteriorly and to preserve a fairly good voice.

The President seemed to have gone the rounds of these various operations and he would have liked to have heard him speak on them at greater length.

Macdonald Critchley, also in reply, said that he would like to make a plea for a most meticulous examination of the nervous system in all obscure cases of laryngeal palsy, because such might be the first sign of a tabes or of several other neurological conditions. As a neurologist one was often asked to see cases of paralysis of the larynx combined with lesions of other cranial nerves. Such cases were probably due to a virus infection. There was no reason why there should not be a virus affection of one single cranial nerve, e.g. the vagus, or recurrent laryngeal. Bell's palsy was probably an example of such. He had no doubt that members were also familiar with cases of recurrent laryngeal palsy in returning prisoners of war from Japan. Many showed signs of nutritional deficiency with bilateral blindness, deafness, dysæsthesia of the extremities, and recurrent laryngeal palsy.

the time of the surgery upon the phalanx itself, although obtaining primary union developed ankylosis of the joint, but the tendons which were bathed in pus recovered their function.

When we come to the systemic dosage of penicillin used I would again state that one is doubtful of the permanency of the cure in the majority of these cases. The average dose was 20,000 units of penicillin administered intramuscularly every three hours day and night for an average of ten to twelve days. Later in the series this dose of 20,000 units was raised to 60,000 units three-hourly, and the results were definitely better.

When we come to the duration of treatment and consider the amount of work that penicillin has to do to reach the organisms within the infected avascular tissue, it is probable that the duration of treatment is nearer to that of subacute bacterial *endocarditis* in which we did not get permanent results until a minimum of twenty-one days was reached.

Local penicillin as an adjunct to systemic penicillin made no difference to the results. In fact the recurrence rate when penicillin was used in addition to systemic penicillin was statistically higher than those who had systemic penicillin only.

Systemic penicillin, therefore, as far as we know, localized infection to the initial site in the bone, and complications were either cured or prevented. This has also been true of prophylactic systemic penicillin as far as our 11 cases can assist us in this opinion.

Primary union has been achieved in the face of infection and the dissemination of infected material prevented. In prophylaxis the uniformly satisfactory results obtained in soft tissue lesions liable to cause an osteomyelitis, and the use of a systemic penicillin "umbrella" in the surgery of infected lesions, should help to lessen the incidence of this disease.

Early diagnosis and early treatment with penicillin will prevent infection of avascular tissue and assist in the absorption and remodelling of infected avascular tissue.

At certain sites in the body owing to the proximity of vulnerable tracts or cavities and in the later stages of the disease, radical extirpation of infected tissue if appropriate and accessible will, under the cover of penicillin, still be necessary. Long incisions and drainage without the removal of infected bone appear from our results to be unwarranted.

It is my conclusion that the future holds great promise for the employment of penicillin in all forms of penicillin-sensitive infections, and this includes infections that happen to alight in bone.

Once more I must pay the greatest tribute to Sir Alexander Fleming and Sir Howard Florey and his co-workers.

I am indebted to the Medical Research Council for penicillin used in this research.

CASE I (X-ray a).—D. G., aged 14. Admitted December 1943 on fourth day of illness. Septic finger two weeks previously. Blood culture *Staph. aureus*, effusion left hip-joint sterile. Pyrexia, severe pain and inflammation upper third of femur. Systemic penicillin. No immobilization. Rapid recovery. X-ray six months after onset. Two years since onset; full function; no recurrence.

CASE I (X-ray a).

It is fit and proper that the results of penicillin therapy should be regarded with the greatest reserve. The vagaries of this disease are only too well known. This is exemplified by one of our own cases who after many vicissitudes and surgical operations, recovered from a gunshot osteomyelitis of the femur in 1918 and remained well for twenty-five years before he spontaneously developed a recurrence of his disease in the fourth year of the Second World War. All of us have known cases to recur at frequent intervals either in the same bone or at unsuspected sites in other bones during the course of the patient's lifetime. It is also our experience that the severity of the disease varies very much from year to year and from patient to patient. In one there may be multiplicity of foci, in another the whole of one bone is affected, and yet another the lesion is localized to a small area in one bone only.

The organism has a peculiar property of hibernation with irregular periods of exacerbation. If the diseased bone is operated upon during the period of hibernation the pathologist is unable to culture the organism, if, however, the patient is operated upon during the period of exacerbation the organism is cultivated with certainty. In both the acute and in the chronic disease the importance of the soft tissue element is apt to be forgotten for there is an extensive change in the soft tissue within the cancellous lattice-work, in the medulla, the periosteum, and commonly in the circum-osseous soft tissue surround.

It is this predominant change in the soft tissue which renders the diagnostic value of X-rays negligible or imperfect, and is the reason that there is a "lag period" in the visible change in the cancellous and compact tissue portraying an event of the past without relation to the present condition of the patient.

For the purposes of discussion I have subdivided these 37 cases into three groups: acute hæmatogenous osteomyelitis, acute recurrent osteomyelitis in which the patient had previously suffered from an osteomyelitis, and subacute recurrent osteomyelitis.

In the latter two groups it is obvious that a gross change has occurred in the soft tissue and in the bone prior to the acute or subacute exacerbation of the disease. This gross change is paralleled by patients submitted to treatment in the late stages of their first attack of hæmatogenous osteomyelitis. It is only in the early stages of acute osteomyelitis that penicillin has its greatest opportunity of assisting the patient.

Our method of treatment, however, in all cases was to institute penicillin and wait and observe the progress of the case. It soon became apparent that penicillin swept the organism from the blood-stream and reduced the acute lesion to that of a chronic lesion. The subsequent fate of the patient depended upon the management of this now chronic osteomyelitis.

This was true of 34 of our 37 cases. The exceptions were 3, a boy of 12 months and a man of 37 both of whom already had bilateral metastatic lesions in the lung and other complications, who died, and a man of 34 suffering from acute osteomyelitis of the os innominatum and head of femur, a failure owing to under-dosage.

Of the 34 remaining cases, in 13 penicillin alone proved successful and so far without recurrence of the disease. In a further 7 as a process of resolution, an abscess formed in the soft tissue and was treated by stab drainage. 2 of these had a subacute exacerbation three months after their discharge from hospital but responded to a second course of penicillin. These 7 cases remain free of recurrence. A total of 20 out of 34 cases.

In 7 further cases the indications were such that under cover of the original course of penicillin the dead and infected bone should be removed. These indications were the proximity of the brain, pleura, or tendon sheaths. All visible dead and infected tissue was removed with primary suture and temporary drainage, and primary union achieved. 1 of these cases had a doubtful subacute recurrence three months later which responded to a second course of penicillin. All 7 remain well.

In 1 other case penicillin and drainage having reduced the acute lesion to the chronic state, and as a deliberate policy, the patient was discharged to be readmitted three months later for extirpation of the now well-demarcated dead bone and primary suture. He also obtained primary union and is free from recurrence.

In the 6 remaining cases an attempt was made to see whether the drainage of bone and soft tissue as a primary procedure under the cover of penicillin would be an improvement upon penicillin only or penicillin and stab drainage. This proved highly unsatisfactory in that generous incisions or multiple drainage which failed to remove all infected bone gave us our worst results. 5 of these 6 cases have a persistent chronic sinus and require radical surgery.

The complications already present in these cases are too varied and numerous to particularize, empyema, jaundice, peri-arthritis infection in many but intra-arthritis infections in only 4 cases of proved certainty. 2 recovered full function of their knee-joint without surgery, and 2 in whom the interphalangeal joints had to be opened at

CASE IV (X-rays a and b).—M. S., aged 10. Admitted November 1943 on forty-third day of illness with request for amputation. Pyrexia and acute spreading inflammation; hand like a boxing glove and forearm grossly swollen, sinuses in palm. Culture *Staph. aureus*. X-ray (a) Systemic penicillin, loose bone and sloughs removed plus local penicillin daily via catheter. Rapid recovery, discharged with one chronic sinus. For deliberate readmission when general condition had improved and lesion well demarcated. Six months later systemic penicillin hemi-diaphysectomy and removal of infected bone, primary suture. Primary union. X-ray (b) one year after onset. Two years and three months no recurrence, soft mobile hand and joints but power equivalent to 30% of normal only.

Dr. J. Trueta reported the results of a series of 30 cases of acute osteomyelitis treated with penicillin over a period of eighteen months at the Wingfield Morris Orthopædic Hospital. The cases were not selected, the duration of the disease before admission varied from thirty-six hours to eight weeks; all of the cases were children except 3 who were over 21. At the beginning of the series the effect of penicillin treatment alone was tried. Adequate immobilization was used, but surgery was withheld. In cases where there was no abscess at the focus, when treatment was begun, penicillin alone cured the disease, provided that the dosage was adequate and the duration of the treatment long enough (1 case in which treatment was stopped after four days when all symptoms and signs had disappeared relapsed but was cured by a second and longer course). In cases where there was already an abscess present at the focus when treatment was begun, the general recovery was slower and even after apparent clinical recovery from the infection the disease could be seen radiographically to spread sometimes for eight to ten weeks before repair began. Pus aspirated from the focus a month after onset showed that staphylococci were still present in large numbers.

The penicillin was therefore supplemented by surgery in the later cases admitted with abscesses and the results were very satisfactory. It was found that if as much pus as possible was evacuated at operation from without the bone and from within by drill holes, no new pus was formed and primary suture was safe. The cases treated in this way recovered from the general infection very much more quickly than those cases with retained pus, and the spread of the disease in the bone no longer occurred, repair began sooner and was more rapid as there was less area of bone involved.

The penicillin in the series was given usually by intramuscular drip. At first 100,000 units in twenty-four hours was used as standard dosage, but with increasing supplies the initial dose was increased to a maximum of 400,000 units in twenty-four hours. It was hoped that with this dosage the bactericidal action of penicillin would be used and the impression was that the initial illness was terminated more abruptly with the high dosage both in the drained and undrained cases. The total dose was not affected by the heavy initial dose as it was found that in these cases the course could usually be terminated earlier. The average dose was 1,000,000 units though it varied from 600,000 units to 3,000,000 units. The shortest effective course was six days, and the longest course was fourteen days.

A standard routine was adopted. Cases admitted without abscess formation were treated by penicillin alone; cases with abscess at the focus were treated with penicillin and with surgery, which included drilling of the bone and primary suture after evacuation of as much pus as possible. Immobilization of the affected part was always used.

The results were encouraging. There was no death in the series. No case developed a metastatic focus, or a local joint invasion after admission. 7 of the cases were suitable for penicillin treatment without surgery, the remaining 23 required surgery. Of these, 2, early in the series, were treated by aspiration alone, and had extensive bone damage. One was readmitted ten months after onset with an abscess connected with the involucrum. Of the 21 wounds, 18 healed without sinus formation, 1 (unsutured) became secondarily infected and required drainage after healing, 2 with extensive bone damage on admission developed sinuses. 4 sinuses persisted, 2 from undrained and 2 from drained cases. There was normal function in 28 of the 30 cases. The exceptions were: an osteomyelitis of femur admitted with septic arthritis of the knee in which the knee range was 5 to 90 degrees; and an osteomyelitis of the humerus of fulminating type admitted thirty-six hours after onset, with involvement of the whole shaft of the humerus; there was full range of movement at the joints but she was still in hospital thirteen months after onset with a persistent sinus.

The results of the treatment of acute osteomyelitis with penicillin were so good that it was fair to say that the disease had been altered and that we now needed a new standard for our results. It was no longer right to congratulate ourselves on a low rate of mortality, metastases, joint involvement and sinuses. There should be no such rate. Improvements would be obtained if patients could be admitted earlier, and now that it was known that there was a cure for the disease if it were treated early, doctors would admit cases for treatment earlier than they had done hitherto; one should no longer wait for the appearance of an abscess. Early cases could be treated by penicillin alone; and might leave hospital, perfectly normal, after three weeks. For later cases, however, surgery was still important, and it should include bone drilling and primary suture.

Dr. Trueta had been impressed by the figure for joint involvement of 25% in a penicillin series where aspiration of abscesses and the metaphyses had been used instead of incision

and drilling, and was himself convinced that so long as cases were admitted with abscesses present, the evacuation of the pus from within and without the bone was an important part of the treatment, in preventing both local joint involvement and spread of the disease through the bone. He stressed the importance of the periosteal blood supply in the repair of the bone, and pointed out that unless the subperiosteal pus was adequately drained, the periosteum was held away from the bone, and could play no part in the repair except to form an involucrum walling off the diseased bone from the external blood supply, and leaving it dependent on the nutrient artery which was probably, at least in part, thrombosed.

Mr. E. C. B. Butler: The treatment of acute osteomyelitis with penicillin may be considered under three headings, the bacteraemia, the toxæmia and the bony lesion.

The bacteraemia.—In 1940 I reviewed the immediate and late results of 500 cases of acute hæmatogenous osteomyelitis admitted to the London Hospital between the years 1918 and 1937. 127 died, a mortality of 25%. In 92 cases a post-mortem was performed, 89 deaths were due to staphylococcal pyæmia, two died during operation and one had bronchopneumonia.

Investigating cases of staphylococcal bacteraemia, many of which were osteomyelitis, Dr. Valentine and I (1943) found that repeated quantitative blood cultures were of considerable value in assessing the immediate prognosis in patients suffering from a persistent blood-stream infection.

In a series of 30 cases we were able to differentiate three groups on a basis mainly supplied by quantitative cultures.

Group 1 consisted of 9 cases of fulminating infection; death occurred in four to five days, colony counts in the blood showed either very high figures 500-1,000 on admission or a rapid rise if the examination was repeated. All died.

In Group 2 the colony count was above 30. The infection was less overwhelming but still serious since only 3 out of 8 cases survived. The deaths took place after three to six weeks from the formation of secondary foci in vital organs particularly the lungs.

Group 3 was characterized by a low colony count of less than 20, the blood usually soon became sterile, there were only 3 deaths in 13 cases, showing that recovery was the rule.

Another point of interest was the presence of a persistent primary focus of infection in cases of acute osteomyelitis associated with bacteraemia. In 1939 we suggested that these foci rather than the infected bone may sometimes be held responsible for the maintenance of the bacteraemia. In severe cases it was our custom to excise or drain these foci in the hope of cutting off the source of the blood infection. In a few cases this treatment appeared to be effective.

The effect of the introduction of the sulphonamides, particularly sulphathiazole appeared to lessen the immediate mortality in our cases. In 15 consecutive cases of osteomyelitis treated with sulphathiazole there was 1 death but only 5 patients had proved staphylococcal bacteraemia which in 1 successful case rose to 97 colonies per c.c. of blood; the patient who died had a colony count of 100 colonies and did not respond to chemotherapy.

Since the introduction of penicillin the story is very different. Altemeier *et al.* (1945) record 34 cases, 20 with a positive blood culture, only 1 died, a late case admitted seventeen days after the onset of the disease. McAdam (1945) describes 40 cases with only 1 death. We have treated 14 acute cases, 7 with a positive blood culture. Unfortunately owing to war conditions quantitative blood cultures were not done on all our patients, the highest figure recorded being 60 colonies. All have recovered.

I have no doubt that the introduction of penicillin has reduced the mortality of this disease from 25% to about 3 to 5% by controlling or preventing the blood infection which so often accompanies acute osteomyelitis and which is the usual cause of death in fatal cases.

Deaths still occur, however, if the diagnosis is not made until pyæmic abscesses have developed in vital organs and are too advanced to respond to treatment. In fulminating cases penicillin therapy should be started within two days if the infection is to be controlled.

Directly the diagnosis of osteomyelitis is made or suspected a sample of blood should be taken for a quantitative culture; the latter, as I have pointed out, indicates the severity of the infection before the commencement of treatment and also provides material for comparison with similar cases treated before the introduction of penicillin.

At present we give an average dose of 100,000 units daily for a period of at least two and generally three weeks. We believe that if the drug is stopped too soon there is a danger of a relapse in the general or local infection.

Small babies tolerate three-hourly injections well but in older children intramuscular drips may sometimes be more satisfactory.

The clinical response is generally rapid, the general condition improves, pulse and respiration fall and the patient's appetite improves. The temperature, however, may persist for some time particularly if there is an undrained focus of pus present in the infected bone or elsewhere in the body.

In our experience the clinical improvement following the administration of penicillin is of a rapid and decisive character not seen in those cases treated with one of the sulphonamides.

We no longer consider it necessary to interfere with the primary focus of infection unless there is a local collection of pus.

Toxæmia.—Before the introduction of penicillin we used to give severe cases intravenous or intramuscular staphylococcal antitoxin which had a high antileucocidin content. This has now been discontinued. Patients should be encouraged to drink plenty of fluids such as glucose lemonade but solid food should not be forced until the child's appetite returns; this generally occurs as soon as the blood becomes sterile.

Small repeated blood transfusions are often useful in the second or third week of the disease to combat the secondary anæmia which is often present in late cases.

Bone lesion.—On admission the affected limb should be immobilized in a splint or splint reinforced with plaster; a complete cast is obviously undesirable at this stage since it prevents repeated examination of the affected bone. Systemic penicillin is then started. We have so far observed 3 clinical end-results.

Group 1: Complete resolution. In these patients the temperature and pulse rapidly return to normal, pain and swelling of the limb disappear in a few days. An X-ray taken in the third week shows either nothing abnormal or else slight subperiosteal thickening. At the end of four weeks the child is apparently quite well; prolonged rest in bed and immobilization of the limb are not required. 3 cases of this type have been treated, they have remained quite well for twelve months after their illness. To achieve this gratifying result diagnosis must be made early and treatment commenced within two or three days of the onset of the disease. Similar results following the use of the sulphonamides were almost unknown.

CASE I.—Girl aged 9.

18.10.44: Four days' pain in the upper thigh, for a week previously she had a boil on the end of her nose.

On admission.—Ill but not delirious child with subsiding boil on her nose. Swelling and intense tenderness over upper third of right femur.

Blood culture: 60 colonies of *Staph. aureus* per c.c. of blood.

Treatment.—Legs immobilized in a double abduction splint. 100,000 units of penicillin given every twenty-four hours for a total dosage of 700,000 units.

At the end of this rather short course her pulse was normal, only slight pyrexia remained, still slight tenderness over femur.

25.10.44: Temperature normal.

1.11.44: All signs of local and general infection gone, X-ray; No evidence of any bone infection.

Home in four weeks. Has remained well since.

Comment.—This patient responded very quickly to treatment. It is difficult to prove she ever had a bone infection but in view of the physical signs I think we are justified in claiming this to be complete resolution of an early case of osteomyelitis.

Group 2: Extensive bone infection without abscess formation. In this group considerable spread of the infection appears to take place judging by repeated X-ray examinations. Decalcification of the bone spreads for the first few weeks despite the temperature and pulse falling to about normal. After a few weeks the bone gradually becomes recalcified but the process is often slow and may take many months. This is not necrosis since the bone does not die. Small sequestra may form but these are apparently sterile and so far have not given rise to any trouble. These cases require much more care than those in Group 1. At present we advise prolonged rest until the bone appears to have recalcified.

Failure to observe this rule in one of our cases resulted in a painless pathological dislocation of the hip in the fifth week of the disease as the patient was lying in bed. Fortunately reduction was easy and the boy is now recovering with a mobile joint. Pathological fracture or a recrudescence of local infection may also occur if movement is allowed too soon. This point is stressed since some writers maintain that cases treated with penicillin do not require to be immobilized. We think this is dangerous teaching in the presence of extensive bone infection. Despite the alarming X-ray picture in this group there is no cause for undue concern provided that plenty of time is allowed for the affected bone to recalcify. The future of these children is still unknown, such cases require to be followed up for at least ten years before any assessment can be made of their deformity or recurrence rate.

We saw similar cases in patients treated with sulphathiazole, but the progress of the disease was slower and the clinical improvement only became manifest after many weeks. In addition these patients sooner or later generally went on to abscess formation.

CASE II.—Boy aged 14.

Four days, fell and hurt his leg. Two days' pain in left thigh with fever.

1.4.45: Admitted to hospital, very ill boy, swelling and tenderness over upper end of left femur, all hip movements limited.

Blood culture: Positive for *Staph. aureus*, no quantitative culture done.

3.4.45: Penicillin therapy commenced. 100,000 units every day for a total dosage of 1,500,000 units.

13.4.45: Developed an abscess at one of the injection sites which was drained.

2.5.45: General condition good, X-ray shows diffuse disease of neck and upper third of femur. Hip movements apparently painless.

17.5.45: X-ray shows diffuse infection but more marked than before, with pathological dislocation of neck of femur. This was at once reduced and a hip spica put on.

24.5.45: X-ray shows complete reduction.

Remained in plaster until 7.11.45. General condition excellent and after removal of plaster hip movements were possible. At present he has not been allowed to bear weight on the leg but his function is steadily improving.

Comment.—This case illustrates the importance of maintaining immobilization in this type until the danger of dislocation or fracture is over.

CASE III.—Boy aged 14.

Two weeks' boils on neck. Three days' pain in the left hip.

On admission (19.2.45).—Ill boy with temperature 104° and pulse 130. Left thigh swollen and tenderness over upper femur and pelvis. Hip movements impossible from pain.

Blood culture: Positive to *Staph. aureus* but no quantitative culture done.

Treatment.—Leg immobilized in abduction splint with traction. Penicillin 100,000 units daily for a total dosage of 1,000,000 units. During this course his condition improved but his temperature did not settle.

X-ray showed normal femur but area of infection in acetabulum.

14.3.45: Temperature normal, felt quite well. Hip spica applied.

9.5.45: X-ray showed that head of femur was impinging into the acetabulum in an attempt to produce a central dislocation. Traction applied.

7.11.45: Out of plaster, hip fixed with commencing ankylosis.

Present condition.—No recurrent infection; hip fixed; weight bearing not yet permitted.

Comment.—Response to penicillin therapy good but the treatment did not prevent destruction of the hip with ankylosis. In cases of joint involvement from the pelvis intramedullary penicillin would be impossible and it would be difficult to prevent destruction of the joint although local injections of the drug into the joint might have helped in this case to limit the arthritis.

Group 3: Formation of subperiosteal or intramedullary abscesses. In a certain proportion of cases, 7 in this series, an abscess forms in the soft parts or inside the medulla. This can be diagnosed either by fluctuation or persistent bone pain which indicates intra-osseous tension.

If the abscess is a small one it can either be aspirated or drained by a small incision and recovery is usually rapid.

If the abscess is large or tension is present in the bone then operation is indicated. In 3 cases we have drained an abscess, in 2 more the bone was also drilled. After-treatment has consisted in a light dressing with vaseline gauze, the limb being supported in a splint. At the end of a week the wound has been inspected and routine cultures have usually shown no organisms. Secondary suture has then been performed, 3 have healed perfectly but 1 has a small persistent sinus. After the secondary suture we have put 5,000 units of penicillin twice daily via a small rubber tube into the wound for five days but this is probably not essential provided that the patient is still on systemic treatment. The best time for secondary suture is from the fifth to the seventh day; if the wound is left open for a longer period suturing becomes more difficult and secondary infection is liable to occur. To those of us who were familiar with the method of repeated changing of offensive plasters it is nothing short of miraculous to see these children lying in bed with soundly healed limbs two weeks after the drainage of an acutely inflamed bone. The day of the stinking plaster has, we hope, gone for ever in this disease.

The length of time patients in this group should be immobilized depends on the radiographic evidence of the amount of bone involved. So far we have found that patients in this group do not need such prolonged rest as those in Group 2. Sufficient cases, however, have not been treated to draw any definite conclusions on this point.

One patient, an adult, was referred to the London Hospital with the diagnosis of Ewing's tumour of the femur because his pain and temperature did not respond to systemic penicillin. We were able to drain a large abscess round the shaft of the femur which relieved his pain and fever. Systemic penicillin was restarted and successful secondary suture performed in ten days' time. If an abscess is present pyrexia will not subside until the pus is let out.

CASE IV.—Girl aged 8.

Five days' fever with four days' pain in the knee.

4.8.45: Admitted in delirium with a pleural rub at both bases and swelling of the left ankle and knee. Admitted as a query rheumatic fever.

Blood culture: Heavy growth of *Staph. aureus* but unfortunately no quantitative culture performed.

Treatment.—Penicillin 100,000 units daily for eighteen days.

9.8.45: First seen in the medical ward. Knee swollen and signs of infection of the tibia. Leg immobilized.

15.8.45: Clinically improved, appetite returned but obviously a large abscess over the tibia. Knee aspirated. Fluid sterile. Large abscess drained which had burst through the periosteum. Bone drilled in two places, some pus in medullary cavity. The pus was sterile.

22.8.45: Secondary suture performed with 4,000 units penicillin solution locally twice a day for five days.

29.8.45: Stitches out, only small sinus remained.

30.8.45: X-ray showed infection upper third of tibia.

7.11.45: Completely healed with full function of knee.

January 1946: Well; walking perfectly; wound soundly healed.

Comment.—This child was severely ill with a fulminating blood infection; it is safe to say that she would have died before the introduction of penicillin. It was interesting to find the abscess when drained was sterile, and the response to secondary suture was very satisfactory.

Four of our cases had infective arthritis; the hip was infected in two of them, one developed pathological dislocation and the other became ankylosed. Diagnosis was not apparent until X-ray examination showed involvement of the joint. Local treatment consisted in a hip spica. McAdam states that intramedullary penicillin given via a needle may diffuse through the infected femur into the hip-joint; if this is so it will be a valuable aid to treatment in cases of infection of the femoral neck, but this form of therapy will not be applicable to cases of arthritis secondary to pelvic infection.

In the other 2 cases the knee was involved, diagnosis being made by finding the organisms in the joint exudate.

Treatment consisted in repeated aspiration with injection of 5,000 units of penicillin into the joint. One recovered with full function, the other has a stiff knee with commencing ankylosis.

Local penicillin will rapidly sterilize a joint but the ultimate functional result depends first on the rapidity of the diagnosis and secondly on the state of the articular cartilages after the infection has died down. Destruction of these will as a rule produce ankylosis.

CONCLUSIONS

- (1) That penicillin therapy has reduced the mortality of acute osteomyelitis from 25% to about 4%.
- (2) That if penicillin is used during the first few days of the disease complete resolution may occur.
- (3) If resolution does not occur then immobilization of the affected limb should be prolonged in those cases showing extensive bone involvement.
- (4) If operation is required secondary suture can be safely done at the end of a week. There is no longer any justification for the closed plaster treatment in this disease.

Section for the Study of Disease in Children

President—Professor NORMAN B. CAPON, M.D.

[January 25, 1946]

Demonstration by Dr. A. W. G. Ewing and Mrs. Ewing

of the methods of ascertaining deafness and partial deafness in children under 5 years of age. Children were brought to take part in the demonstration by kind arrangement of Mr. T. E. Cawthorne and of Miss O. Beatson, headmistress of the Tottenham School for the Deaf. Audiometric tests of older children were also made.

[February 22, 1946]

DISCUSSION ON NEONATAL INFECTIONS

Dr. Beryl Corner: With some notable exceptions, paediatricians have largely devoted themselves to the problems of infancy which occur after the first two or three weeks of life. It has become increasingly clear that, since the foundations of infant health are laid in the first few weeks of life, the study of the neonatal period is of great importance, and one of the first problems that confront the paediatrician is that of neonatal infection.

In children's hospitals, infant infection is considered largely in terms of gastro-enteritis and respiratory infections, but when the neonatal period is studied, rather a different problem presents itself, since pathogenic staphylococci are responsible for so many of the lesions. When staphylococci are referred to in this paper, the coagulase test has been positive in each case.

INCIDENCE OF INFECTION

An analysis was made of 6,534 consecutive live births in two maternity units in Bristol.

The death-rate from infection in Hospital A is 0.89 per 1,000 live births, and that in B is 3.76 per 1,000 live births. Although this is not a very high mortality figure when one considers the other causes of neonatal mortality, there is a considerable incidence of infection—25.3% of all babies in Hospital A and 29.7% in Hospital B.

Eye infections account for more than twice as many cases as any other single cause. In Hospital A there is a very accurate system of records, and therefore a number of cases are included in this figure in which the eye abnormality was extremely slight and only lasted twenty-four hours, perhaps hardly warranting the term "infection". All cases where there was any discharge were swabbed and, with the exception of two gonococcal cases, *staphylococcus aureus* and diphtheroids were found. Only 89 cases occurred within the first five days of life; all the rest were in the second week. The two gonococcal cases occurred on the third day. In Hospital B three cases were gonococcal.

Staphylococcal infections of the skin are the second large group. These range from the solitary pinhead pustule to the large abscess or carbuncle. Infection of the fingers is common, but most cases were trivial. In Hospital B several cases required incision and one infant developed a tendon sheath infection and was left with a flail finger. The commonest cause of abscesses was the injection of oily vitamin K preparations. Since the use of watery vitamin K there has been no injection abscess in either hospital. Other abscesses occurred in the breasts, and subcutaneous tissues often following pustular dermatitis. Trauma from forceps was responsible for some abscesses on the scalp. In two cases areas of bone half an inch in diameter were exposed. The two carbuncles were serious infections, one being on the chin and the other on the cheek.

Mouth infections were all very slight in Hospital A; In only two cases was there any difficulty in sucking in consequence and no other constitutional symptoms. In Hospital B there were several cases with constitutional symptoms, inability to swallow and vomiting.

In Hospital A during the period under review there was quite an extensive outbreak of colds; nearly all nasal infections included occurred during this epidemic, which was undoubtedly aggravated by the fact that at the time all the infants were being taken in small baskets to an air-raid shelter with no outside ventilation. Despite this, only 27 cases of bronchitis developed in these infants. Three infants developed pneumonia in this hospital, all of whom died. One was a premature baby whose mother had started to breast-feed it and unfortunately developed a cold; one infant had a serious congenital heart lesion and caught a cold during the epidemic; the third was a normal baby who developed massive collapse of one lung on the tenth day, and died, with early bronchopneumonia found at post-mortem.

In Hospital B the incidence of bronchopneumonia is higher and fell largely on premature babies who form the bulk of the mortality figures. One child developed a staphylococcal empyema.

Only one case of diarrhoea occurred in Hospital A. This was in a 4-day-old infant whose mother had gastro-enteritis during labour. The infant responded quickly to treatment.

In Hospital B gastro-enteritis has been a considerable problem. It has occurred in numerous small outbreaks affecting most of the infants in the nursery and coinciding with gastro-enteritis in the mothers. There were 5 fatal cases, and in two outbreaks several infants required intravenous fluids. No specific organisms were isolated from stools of mothers or infants.

Suppurative arthritis of the hip-joint occurred in one infant with numerous staphylococcal skin infections.

PREVENTION OF INFECTION

From these figures it is obvious that the prevention of infection is a major problem.

In Hospital A, three or four years ago a serious effort was made to reduce infant infections. The problem was approached from the standpoint of preventing staphylococcal infection, particularly of the skin, and as a result it was found that other infections, such as gastro-enteritis, had also become much less frequent. Two factors are of paramount importance in producing lesions in the infant. First, the human carrier of staphylococci, as has been demonstrated by Knott and Blaikley, and, secondly, minute trauma to the infant's skin or mucous membranes.

As long as pustules on a newborn infant's skin are dismissed lightly as "a few septic spots", so long shall we continue to get serious or fatal staphylococcal infections in the nursery.

As a case example: an infant weighing 6 lb. 12 oz. and healthy at birth, developed a very mild conjunctivitis and a few pustules on its abdominal skin during the first week, without much attention being paid to them. During the second week weight was stationary for no apparent reason, but the child regained its birth-weight with complementary feeding. At the end of the third week the infant began to lose weight steadily, and after three days the mother took him home against medical advice. On discharge he appeared pale, but no investigations beyond test-weighing had been done. He was readmitted five days later, slightly jaundiced, with pyrexia, and having lost nearly a pound in weight. He died shortly after admission; a blood-count and rhesus compatibility tests were performed just before death and revealed no evidence of hæmolytic anaemia. Post-mortem by Professor Hewer revealed umbilical sepsis, with thrombosis of umbilical veins, focal necrosis of the liver and focal pyelonephritis, probably a blood-borne infection, all resulting from the few spots on the abdomen.

The importance of apparently trivial infections can best be brought home to the nursing staff by the keeping of accurate infant records. These may take the form of a chart, or I prefer for simplicity, a notebook in which each baby has a page for daily details of its progress and treatment; abnormalities being entered as soon as they are found. The doctor should be trained as a medical student by giving instruction in routine care of the newborn in weekly clinical rounds devoted entirely to the infants, during his midwifery clerking.

The nursing staff.—The idea is tenaciously held in many circles that the mother and baby are one inseparable unit and that the same nurse should care for both. This unit of mother and baby was the ideal in the days of private domiciliary midwifery when one nurse did all that was required for one mother and baby; but in these days of large-scale institutional midwifery, with the forty-eight-hour working week and the large number of lectures and clinics to be attended by the pupil midwife during her six months of training, insufficient emphasis has been laid by hospital authorities on the amount of time that is required for adequate care of the infants. It must be realized that, even in the smallest training units, every patient must be handled by a minimum of four nurses during the week. Thus any attempt at nursing mothers and babies in small units to imitate the domiciliary system tends to break down owing to lack of sufficient nurses.

I would urge that the babies be nursed by a completely separate nursing staff. This has the following advantages:

- (1) The nurse's whole attention is focused on the baby and thus minor lesions are readily observed and receive the maximum care.
- (2) The baby's routine is undisturbed by the maternal emergencies of the department, which are often many, and the nursery need never be left unattended.
- (3) The carrying of infection from mothers to babies is largely eliminated.
- (4) Use may be made of other types of nurses than the midwife or pupil-midwife for much of the routine work, and thus the pupil-midwife may concentrate on doing her essential work well.

Where should the baby be nursed?—Nursing with the mother in single rooms should theoretically help to prevent infection, but, since this involves a good deal more work for the nursing staff, the actual handling of the child may be carried out more roughly and quickly, with more liability to trauma and with a greater tendency to scamp details

of aseptic technique. In addition, it is more difficult for the Sister to supervise the work of pupil-midwives. At the present time it seems more practical, in large maternity departments, to nurse the infants in special nurseries, paying particular attention to details of nursing technique.

SPECIAL TECHNIQUE

In Hospital A the following details of technique have been devised:

(1) *The nursery lay-out.*—50 or more babies are all nursed in one nursery. The nursery is a long, narrow room which is partially divided into three sections. The inner part is separated from the rest of the nursery by a wall with a doorway leading into the main room. This section is the warmest part, usually being kept at a temperature of 70° to 75° F., and relatively free from draught, so that all babies spend their first three days there. They then move on to the central part of the room, where they spend their second week, going out on to the balcony whenever weather permits.

All equipment and linen for use of the babies is kept in the nursery, where all toilet and feed preparations are carried out.

(2) *Nursery staff.*—There is a special nursery staff who spend their entire time in the nursery and have no other duties. This comprises a Sister, staff midwife, one nursery trained nurse and two nursery probationers during the day, with a staff midwife and two probationers or nursing auxiliaries at night. Pupil-midwives spend a week or so of their training working in the nursery. All staff have nose and throat swabs taken and wear masks.

The nursery probationers are usually girls of 16 to 18 years of age who spend six months resident in the hospital before proceeding to nursing training in one of the other hospitals in the city, where most of them have already been accepted before coming to the Maternity Hospital. Their duties include the changing of all normal babies over 3 days old, cleaning nursery, carbolicizing, and making up of cots, preparation and clearing away of bathing apparatus, care of infants' clothes. They are invaluable members of the nursery staff, since they take over so many routine duties that the trained staff are free to care for the very young and abnormal babies. They have been found to be particularly alert about reporting slight abnormalities.

I attribute our absence of gastro-enteritis or serious skin sepsis largely to this special staff arrangement.

The babies are taken to the mothers for feeding by the ward staff and pupil-midwives who supervise all feeds.

(3) *Routine care.*—All normal infants are bathed after birth and daily from the fourth day. The bathing is done in the early morning by the staff and pupil midwives of the wards before they handle the mothers. The nurses all bath together, usually nine or ten at once, and each baths four or five babies. Each nurse has her own complete bathing outfit which she alone uses. Portable enamel baths are used which can be easily sterilised, and the nurse washes her hands in a separate bowl after undressing the baby, before starting to bath.

The bathing book is a special feature designed to check infection. The name of each pupil or staff midwife is entered daily with the names of the infants she baths. She baths the same infants and in the same order daily. Thus, if any infection occurs, it can be readily traced to a possible carrier among the nursing staff, and other babies tended by that nurse can be carefully observed.

Nursery Sister supervises bathing and trains the pupils. Ward Sisters collaborate with her closely by reading the infant report books daily and examining all babies during bathing on the tenth day and later, on the day of discharge.

After the first cleansing of eyes and mouth at birth, no routine eye, mouth or nose toilet is done. Cord powder and cotton binders are sterilized before use.

An abundant supply of easily laundered and preferably sterilizable clothing is essential, so that no soiled clothing shall remain in contact with the skin.

Since the newborn infant makes aimless wanderings of the hands and frequently scratches the face, poking the eyes and nose, the hands and arms are kept away from the face by a special form of cotton wrapper. This enables the chest to move freely and allows the baby's arms to move up and down, but not out of the wrapper. The infant has a clean wrapper at least once a day and as often as it is soiled. Septic spots on the skin frequently start as a sweat rash. No blanket ever touches the baby. Blankets spoil with frequent laundering and become harsh and tend to chafe the skin. Thus a slightly soiled blanket may be retained in use, and as it cannot be easily sterilized, may be a source of spread of infection. At birth, therefore, the baby is received in a blanket which is completely covered by a soft sheet, and a napkin is wrapped round the arms and trunk so that the infant cannot contaminate its face. In the cot, a small blanket is

enclosed in a pillow-case and this covers the infant loosely; for feeding the child is wrapped round with this pack.

Soiled napkins and clothes are placed in covered pails and after each changing these are tipped into a large bin which is kept on the fire escape outside the nursery and removed from there by the laundry staff. No soiled clothes or napkins are sluiced or washed by nurses.

In view of the danger of epidemics in such a large nursery, the slightest suspicion of infection of skin, eyes, nose, or mouth is reported at once to nursery Sister and recorded on the infant's record page. The baby is immediately barrier-nursed, and when a more severe infection is suspected, such as an impending pemphigus, gastro-enteritis or bronchitis, it is removed at once to isolation.

Barrier-nursing is performed in one corner of the nursery near the balcony. The baby is handled by the Sister or staff-midwife only. A gown is kept on the cot and always worn before handling the cot or the baby. A table reserved for the purpose is placed beside the cot and the whole screened off. All articles for toilet or treatment of the baby are kept on the table.

Further precautions that are taken to prevent infection include the barrier-nursing of all infants whose mothers have any rise in temperature, and the wearing of masks by these mothers when feeding the babies.

Following the epidemic of colds it was decided to start all infants on vitamins C, A and D on the third day, and this has been done since.

The feeding of the baby plays a considerable part in preventing infection. 85 to 90% of babies in both these hospitals are fully breast-fed on discharge, and all babies receive breast-milk only in Hospital B for the first ten days. The mortality from gastro-enteritis has been almost entirely in the hand-fed infant who has received some other food in addition to breast-milk. The greatest mortality is, of course, in the hand-fed premature baby. No epidemic of gastro-enteritis has occurred in these hospitals without there being some coincident infection in the mothers or nurses handling the babies during the period under review. In Hospital A there have been repeated epidemics of Sonne dysentery and other types of gastro-enteritis in mothers and nurses, but none among babies or nursery staff.

TREATMENT

The first point I should like to emphasize is the responsibility of nursery Sister and the great importance of isolating by barrier-nursing every infected infant, however small the infection. And, in the case of eye and skin lesions, nursery Sister should be given power to start treatment at once.

In Hospital A the infant is barrier-nursed in the nursery, unless it is a case of gastro-enteritis, pemphigus, gonococcal ophthalmia or bronchopneumonia, in which case it is removed to an isolation ward with the mother. Here mother and baby are treated as a domiciliary case and one or two nurses only do full-time duty, gloves as well as gown being worn whenever the infant is handled.

In treatment of skin lesions it is important to isolate the lesion from the rest of the infant's skin, and therefore dressings should be used to cover the spot, and whenever it is uncovered the clothes and surrounding skin should be protected by a dressing towel. One so frequently sees septic spots on the head, for instance, being rubbed against the sheet and thus contaminating other areas of skin.

The application I have found most useful for skin lesions has been a paste of 5% sulphathiazole in glycerine. This is applied to the lesion every time the infant is fed or changed and the majority of pustules will clear in twenty-four to forty-eight hours if this is carried out conscientiously. In the one case of pemphigus in Hospital A, no fresh lesions were present after forty-eight hours and the skin was healed in five days.

Penicillin cream, 400 units/gramme Lanette wax, has been used in 31 infants with pustular dermatitis or superficial skin lesions. When applied three-hourly it cleared the skin slightly more quickly than the sulphathiazole paste. In several patients, with a number of lesions of the same date, both these pastes were applied three-hourly and the skin cleared equally quickly. This was tried in two cases of pemphigus. The main superiority of penicillin was shown in dealing with abscesses. The two carbuncles each cleared in three days with local application only, and for other abscesses the pus was aspirated and penicillin injected once daily into the cavity. This was used in 11 abscesses, the average number of injections required being three. In 3 cases, intramuscular penicillin was given as well in large doses, twice daily, until the abscess had localized. This treatment avoided incision and constant dressings afterwards.

For more serious infections the use of penicillin appears to be a considerable advance. Pneumonia, fortunately, has been uncommon in my series of cases, but 12 cases have

been treated with penicillin with 3 deaths, all in premature infants. Oxygen tents were used in every case, and sulphathiazole in addition in these three fatal cases.

The following severe cases illustrate the use of penicillin:

One baby developed pneumonia towards the end of its second week, during an epidemic from which three deaths occurred. Six days later it had physical signs suggesting an empyema, and on aspiration thick pus was withdrawn which grew pure culture of *Staphylococcus aureus*. There was also a bronchial fistula. This infant was given intensive systemic penicillin, 20,000 units daily, for fourteen days, and rib resection and drainage were done. It has made a satisfactory recovery.

Another similar case occurred during the fourth week of life in another hospital. Again penicillin intramuscularly was given for two weeks, followed by rib resection and drainage. Complete recovery occurred and the lung fully expanded. This infant is now aged 9 months and has a completely expanded normal chest.

The third instructive case was a premature baby weighing 3½ lb. who developed severe pneumonia on its thirteenth day. It was placed in an oxygen tent and penicillin, 24,000 units daily, by three-hourly injections, was given for twenty-one days until the temperature became normal. A full course of sulphathiazole for five days was also given during this time but made no appreciable difference to the clinical condition or temperature. Oesophageal feeds were given for two weeks and the infant ultimately made a satisfactory recovery. It was fed almost entirely on breast-milk throughout.

The last example of penicillin treatment is the baby with suppurative arthritis.

This infant weighed just under 5 lb. at birth. It developed jaundice due to hæmolytic disease of the newborn during its first few days. On the seventh day a large ulcer appeared inside the upper lip, from which *Staphylococcus aureus* in pure culture was grown. At the same time a whitlow appeared on one finger. The child's condition was poor, although it had previously been transfused, and therefore systemic penicillin was started, 5,000 units daily, by four-hourly injection intramuscularly. The mouth cleared in a few days and the finger was incised. It was in the early days of penicillin and, as the oral swab was negative, the supply of penicillin was stopped. The infant remained feeble, too weak to breast-feed, transfusion wounds then became infected, septic spots appeared on the umbilicus and abdomen. Slight pyrexia continued. About ten days later swelling of the right hip region was noticed, and aspiration withdrew 20 c.c. of pus, pure culture *Staphylococcus aureus*. An X-ray showed intensive involvement of the hip-joint, with osteomyelitis of the upper end of the femur. Daily aspiration and injection of penicillin solution, 500 units/c.c. was then done for ten days, at the end of which time no further pus could be aspirated. The infant left hospital at the end of five weeks, fully breast-fed and thriving. There was a little shortening of the affected leg, and about 75% range of movement was present in the hip-joint.

Professor Arnold Sorsby: *Ophthalmic aspect [Abstract]*.—The incidence of blindness in children aged 5 to 16 years has declined in England and Wales from 36.4 per 100,000 in 1923 to 28.8 in 1933, and 20.3 in 1943. The considerable diminution in infectious disease in childhood is responsible for this decline. The incidence of blindness from phlyctenular ophthalmia and congenital syphilis has gone down considerably, but the most significant reduction has been in blindness from ophthalmia neonatorum. In 1922, 30.4% of all children at blind schools had been blinded by ophthalmia neonatorum. In 1944 the incidence had declined to 9.2%. At the present some 67% of all children at blind schools have been blinded by congenital anomalies including myopia. These congenital anomalies are probably in the main genetic affections, but an unknown proportion are caused by transmitted maternal infections. It is now clear that apart from congenital

enclosed in a pillow-case and this covers the infant loosely; for feeding the child is wrapped round with this pack.

Soiled napkins and clothes are placed in covered pails and after each changing these are tipped into a large bin which is kept on the fire escape outside the nursery and removed from there by the laundry staff. No soiled clothes or napkins are sluiced or washed by nurses.

Professor Arnold Sorsby: *Ophthalmic aspect [Abstract]*.—The incidence of blindness in children aged 5 to 16 years has declined in England and Wales from 36.4 per 100,000 in 1923 to 28.8 in 1933, and 20.3 in 1943. The considerable diminution in infectious disease in childhood is responsible for this decline. The incidence of blindness from phlyctenular ophthalmia and congenital syphilis has gone down considerably, but the most significant reduction has been in blindness from ophthalmia neonatorum. In 1922, 30.4% of all children at blind schools had been blinded by ophthalmia neonatorum. In 1944 the incidence had declined to 9.2%. At the present some 67% of all children at blind schools have been blinded by congenital anomalies including myopia. These congenital anomalies are probably in the main genetic affections, but an unknown proportion are caused by transmitted maternal infections. It is now clear that apart from congenital

syphilis, toxoplasmosis and German measles in the mother can produce extensive ocular lesions in the offspring. Whooping-cough may also be a factor.

The most clearly recognised neonatal infection is ophthalmia neonatorum. There is no reason for assuming that ophthalmia neonatorum itself has declined to any extent, but the reduction in the incidence of impaired vision and blindness from ophthalmia neonatorum is brought out by the following typical rates per 100,000 births:

ENGLISH COUNTY BOROUGH		
Year	Impaired vision	Blindness
1924	24.2	4.0
1934	6.0	1.0
1943	1.4	0.5

Statutory notification, introduced in 1914, together with the provision for necessary treatment, must be regarded as the main cause for the gratifying decline in the incidence of impaired vision and blindness. It is not certain that the use of prophylactic drops, which is part of the Credé procedure, is a significant factor, but it would appear that the organic silver preparations are as effective as silver nitrate itself. General sulphonamide therapy has revolutionized the treatment of ophthalmia neonatorum. Clinical cure can be obtained within three days in some 30% of cases, whilst over 80% have recovered within eight days. Of the sulphonamides sulphamezathene is the most generally useful. Even better results can be obtained by the local use of penicillin. Frequent applications in adequate concentration are essential. Cure in most cases can be achieved within a matter of hours.

Ophthalmia neonatorum to-day is not mainly gonococcal infection. Only some 25% of cases are gonococcal. At least 10% are caused by a virus, which is responsible for a *virüs cervicitis* in the mother. The staphylococcus is the commonest organism being responsible for some 35% of cases, but many other organisms are found. Both bacterial and virus ophthalmia neonatorum respond readily to the sulphonamides and to penicillin. Though the complications of ophthalmia neonatorum are now well under control, there is still much to be done in eliminating the affection itself. Essentially this is a problem of ante-natal care.

SORSBY, A. (1945) *Ophthalmia Neonatorum*. London.

Dr. Elaine Field gave preliminary results of a small-scale investigation being carried out at University College Hospital on the prophylaxis of skin infections in the newborn. Fischer (1944) recorded good results after swabbing the babies from the fifth day with a lotion containing 0.16% of cetyl trimethyl ammonium bromide (CTAB). He found cottonseed oil and sterilized peanut oil less satisfactory prophylactic applications.

Dr. Field therefore decided to try prophylactic swabbing of the babies from birth with a similar CTAB solution as well as a series using penicillin cream (*see below*). There

Penicillin Cream		Cetyl Trimethyl Ammonium Bromide (CTAB)	
Lanette wax S.X.	2½ ounces	Arachis oil	4
Paraff. melle flav.	1 ounce	Celofas W.F.Z.	1.25
Arachis oil	3 ounces	Boric acid	2.0
Buffer solution	2½ ounces	CTAB	0.2 (later reduced to 0.1)
Distilled water	to 1 gallon	Water	to 100.0
with chlorocresol	35 grains		
Sterilized by autoclave then penicillin solution added daily as required to make 200 units per ml.		Sterilized by autoclave.	

are about a thousand deliveries a year at the hospital and the babies are nursed in four nurseries, each containing approximately ten babies. Nurseries A and B are on the same floor with the same nursing staff, nurseries C and D are on different floors with different nursing staff. In nursery A the babies were swabbed all over from birth daily with penicillin cream, nursery B was used as a control, the babies being washed daily as usual. In nursery C babies were swabbed with CTAB solution and nursery D was used as a control with daily washings. The investigation has been in progress for about a year during which time the nursing staff have been instructed to report any pustule or inflammation of the skin; sore buttocks have not been included.

RESULTS

Nursery A (Penicillin cream)—No infections.

Nursery B (Control)—Three infants with infections—Mild.

Nursery D (Control)—Five infants with infections—Mild.

Nursery C (CTAB for nine months)—Eight infants with infections—some severe. (Penicillin for three months)—No infections.

In nursery C Sister reported that the CTAB appeared to irritate the skin so penicillin cream was tried instead and no infections have since been reported.

President—W. A. Pool, M.R.C.V.S.

[February 20, 1946]

DISCUSSION: INTESTINAL DISORDERS OF THE NEWBORN

Dr. Robert Cruickshank: I shall discuss only the *diarrhoeal* disorders of the newborn and include, for the sake of comparison data on the enteritis of infants past the neonatal period. There are three main points which I should like to put forward: (1) That the infant is prone to infection with endogenous bacteria; (2) that such infection is facilitated by adverse environment; and (3) that the infant is ill-adapted physiologically and immunologically to deal with infection.

(1) *Endogenous infection*.—By endogenous bacteria is meant those organisms—staphylococci, pneumococci, monilia, coliform bacteria—which very early in life become resident on the skin, in the nose and upper respiratory tract and in the intestine, and which in the older healthy child have little power to invade or infect. *Staphylococcus aureus* is present in the nose of 80% to 100% of babies in the first few weeks of life and is responsible for most of the mild infections of conjunctiva and skin which are so frequent in the neonatal period (outbreaks of pemphigus neonatorum may be due to more virulent "epidemic" strains of the staphylococcus). From these localized infections dissemination to deeper tissues may occur, causing pneumonia, osteomyelitis, or septicæmia, with serious consequences for the infant. Sometimes *Staphylococcus albus* is isolated from the blood in such numbers as to indicate that it, too, may produce generalized infection in the susceptible infant. Pneumococci are present in the upper respiratory tract of 30% to 60% of infants and certain types (for example 4, 6, 19 and 23) predominate in the early period of life. These are the types which are also most frequently isolated from infants with pneumococcal infection (otitis media, bronchitis and bronchopneumonia) and one or two of these types may predominate in an infected community (Hendry, 1942). Thrush is an infection which is more frequent in early infancy than is usually realized. Clinical infections have been shown to occur in 4% to 5% of infants in the first ten days of life, and can cause considerable upset in the neonatal period by interfering with feeding; when the infection extends to the œsophagus and stomach, more severe symptoms, e.g. anorexia, blood-stained vomiting and even death, may follow. Both latent and clinical infections are three to four times more frequent among artificially-fed than among breast-fed babies, probably associated with the greater risk of contact infection from bottles, teats, nurses' hands and the like (Ludlam and Henderson, 1942). Spread of these potentially pathogenic bacteria is facilitated by propinquity and overcrowding, so that in the case of an organism with a multiplicity of types one or two particular types may be isolated from a group of children who are in close contact with each other. When through adverse environment infections occur, these particular types will be found to be responsible for the lesions and may give the impression that the infection was due to an "epidemic" strain of the organism.

When infantile diarrhoea is considered in the light of these findings it at once becomes noteworthy that this disease is much more frequent and more severe in artificially-fed than in naturally-fed babies, in-common with a high content of coliform bacteria in the intestine of the artificially-fed child and their rarity in the bowel of the breast-fed baby. Thus, in an outbreak of neonatal diarrhoea in a maternity unit where at the time only 12 of 30 babies were wholly breast-fed, these 12 babies alone escaped infection; the remaining 18 all developed diarrhoea and all died (Sakula, 1943). In another outbreak (Ormiston, 1941), the fatality rate among the breast-fed infants was 14% and among those artificially-fed 60%. Similarly in gastroenteritis of older infants only 5% to 10% of the cases occur among breast-fed children, and breast-feeding even for a few weeks seems to give the baby an added resistance in overcoming infection (Gairdner, 1945). That certain Gram-negative coliform organisms may be especially incriminated in the causation of infantile enteritis is suggested by the early work on summer diarrhoea by Morgan and Metchnikoff, both of whom reported a high incidence of proteus types. Lately Sakula has found *Ps. pyocyanea* unusually common in cases of neonatal diarrhoea, and Bray (1945) reported the recovery of *Bact. neapolitanum* from over 90% of cases of gastro-enteritis in older infants. Obviously, a reliable classification of the coliform group, either serologically or by phage typing, is needed to determine whether specific types have, like certain pneumococcus types, the capacity to spread and to initiate infection when resistance is lowered. Progress towards this end was made by the early work of Kauffmann and lately by Vahne (1945) who

syphilis, toxoplasmosis and German measles in the mother can produce extensive ocular lesions in the offspring. Whooping-cough may also be a factor.

The most clearly recognised neonatal infection is ophthalmia neonatorum. There is no reason for assuming that ophthalmia neonatorum itself has declined to any extent, but the reduction in the incidence of impaired vision and blindness from ophthalmia neonatorum is brought out by the following typical rates per 100,000 births:

ENGLISH COUNTY BOROUGHs		
Year	Impaired vision	Blindness
1924	24.2	4.0
1934	6.0	1.0
1943	1.4	0.5

SORSBY, A. (1945) *Ophthalmia Neonatorum*. London.

Dr. Elaine Field gave preliminary results of a small-scale investigation being carried out at University College Hospital on the prophylaxis of skin infections in the newborn. Fischer (1944) recorded good results after swabbing the babies from the fifth day with a lotion containing 0.16% of cetyl trimethyl ammonium bromide (CTAB). He found cottonseed oil and sterilized peanut oil less satisfactory prophylactic applications.

Dr. Field therefore decided to try prophylactic swabbing of the babies from birth with a similar CTAB solution as well as a series using penicillin cream (see below). There

Penicillin Cream		Cetyl Trimethyl Ammonium Bromide (CTAB)	
Lanette wax S.X.	2½ ounces	Arachis oil	4
Paraff. melle flav.	1 ounce	Callofas W.F.Z.	1.25
Arachis oil	3 ounces	Boric acid	2.0
Buffer solution	2½ ounces	CTAB	0.2 (later reduced to 0.1)
Distilled water	to 1 gallon	Water	to 100.0
with chlorocresol	35 grains		
Sterilized by autoclave then penicillin solution added daily as required to make 200 units per ml.		Sterilized by autoclave.	

are about a thousand deliveries a year at the hospital and the babies are nursed in four nurseries, each containing approximately ten babies. Nurseries A and B are on the same floor with the same nursing staff, nurseries C and D are on different floors with different nursing staff. In nursery A the babies were swabbed all over from birth daily with penicillin cream, nursery B was used as a control, the babies being washed daily as usual. In nursery C babies were swabbed with CTAB solution and nursery D was used as a control with daily washings. The investigation has been in progress for about a year during which time the nursing staff have been instructed to report any pustule or inflammation of the skin; sore buttocks have not been included.

RESULTS

Nursery A (Penicillin cream)—No infections.

Nursery B (Control)—Three infants with infections—Mild.

Nursery D (Control)—Five infants with infections—Mild.

Nursery C (CTAB for nine months)—Eight infants with infections—some severe.

(Penicillin for three months)—No infections.

In nursery C Sister reported that the CTAB appeared to irritate the skin so penicillin cream was tried instead and no infections have since been reported.

lack is in the capacity to produce new antibody which, recent research indicates, may be derived principally from the lymphocytes, and the great lymphocytic activity in the first few years of life is probably an indication of the infant's efforts to make good this deficiency. The resistance of the breast-fed child to endogenous infection raises the question as to whether it derives maternal antibody through suckling. Objective evidence is mostly negative. Human colostrum, unlike that of sheep or cow, is low in antibody-content and there is no increase of diphtheria antitoxin in the infant's blood as a result of suckling (Kuttner and Ratner, 1923). Yet, Gröer and Kassowitz (1919) claimed that diphtheria antitoxin persists longer in the blood of the breast-fed than of the artificially-fed child, and clinical experience suggests that breast feeding gives the infant a greater resistance to infections, e.g. bronchopneumonia, other than enteritis. This is a matter for further study. Meanwhile it may be claimed that in the present social conditions breast feeding by 80% of mothers for six months—surely an attainable objective—would materially reduce the mortality from infantile enteritis.

Dr. R. Lovell: The intensive breeding of domesticated animals and the unnatural methods of rearing and feeding which are necessary because of economic conditions take a heavy toll of the newly born. The infective agents which cause the actual death of the animals are often of low pathogenicity and even harmless in adult stock. These agents assume a pathogenic rôle when the delicately balanced equilibrium which a newly born animal has to establish with the outside world is upset. This equilibrium is easily upset when modern economic conditions have a tendency to interfere with the normal processes of nature. One example may be taken from the dairy industry whereby calves are removed from the mother at birth so that more milk may be available for human use. It is therefore necessary to consider the probability that not one but a multiplicity of causes are frequently involved in these diseases. Diseases of the newborn thus may not always be introduced from outside but often result from an upset in the balance established between an animal host and the prevalent bacteria. I have selected two of the common, well-known disorders of young stock for the introduction to this discussion, lamb dysentery, and white scours of calves.

Lamb dysentery.—This is a well-known disease of young lambs which is frequently fatal and has been recognized for many years in certain areas in the Border Counties of Scotland and England. It is now known to exist in very much wider areas and occurs not only in Great Britain but also in other parts of the world. Lambs up to one week of age are most often affected but it has been found in lambs up to about three weeks old. Infection appears to be by ingestion of *Clostridium welchii* type B, and the specific lesions are found in the intestine and vary from small discrete ulcers to large areas of necrosis of the wall of the intestine. At the beginning of an outbreak a few of the newborn lambs only may be infected, but there is often some apparent increase in the virulence of the organism and there is a higher frequency of the disease in lambs born later in the year. On the other hand this may be associated with a greater weight of infection.

It is well known that *Cl. welchii* type B is a toxin-producing organism and that treatment of lambs is not practicable. Two methods of prophylaxis are available: (1) Vaccination of the ewe. The vaccine consists of a formalinized culture of the causal organism and ewes are injected during the autumn and again about ten days before lambing is due to begin. The ewe thereby obtains an active immunity and antibodies are transmitted to the lamb by the ingesting of colostrum. The mucous membrane of the intestinal tract of the lamb is permeable to these antibodies for the first few days of its life, and the lamb is protected during the susceptible period.

(2) Lambs may be injected within a few hours of birth with lamb dysentery serum prepared in horses and a passive immunity is thereby induced by artificial means in the lamb; but this method of prophylaxis is not as practicable as vaccination of the ewe.

Although that is briefly the story of lamb dysentery it is as well to remember that there are causes which predispose to the disease, and these were more freely discussed when the aetiology of lamb dysentery was obscure. Lambs which suck well and overload themselves with milk appear to develop the disease more often than those

has subdivided the coliform group into some 115 types on the basis of O (somatic), K (capsular) and H (flagellar) antigenic analysis. Vahlne found a high incidence of two or three groups among coliform strains isolated from cases of cystitis, appendicitis and cholecystitis, and so it may be that certain coliform organisms will come to be recognized as more potentially pathogenic than others.

Another common organism in the intestinal flora of the artificially-fed baby is *Str. faecalis* or the enterococcus. In this connexion there may be significance in the work of Gale (1944) who found that some strains of *Str. faecalis* were active producers of tyramine from tyrosine, and that tyramine was toxic to young rats which had not yet developed a specific detoxicating enzyme. Babies in the first few months of life also lack this enzyme, and as active tyramine-producing strains of *Str. faecalis* have been found in the stools of babies with neonatal diarrhoea, it was suggested that these organisms may be causally related to the condition. My colleague Mrs. Helen Tomlinson (*née* Epps) has followed up this promising inquiry by examining the enzymic activities of a large series of coliform organisms from babies with diarrhoea and from normal cases, but so far has found no evidence of the production of toxic amines similar to those produced by the enterococcus.

No discussion of the aetiology of infantile enteritis would be complete without reference to the viruses. Two claims have been made for the isolation of a virus-like agent from infants with diarrhoea. Light and Hodes (1943) were able to induce diarrhoea in calves with filtrates of faeces from cases of neonatal diarrhoea. The causative agent was peculiar in that it could withstand heat at 100°C. for five minutes and the possibility that a natural virus of calves was being activated could not be ruled out. Buddingh and Dodd (1944) have described a syndrome of stomatitis and diarrhoea in infants from whose mouth lesions a virus-like agent was isolated, but the syndrome does not correspond with the usual type of gastro-enteritis seen in this country. Another infection characterized by nausea, vomiting and profuse watery diarrhoea has lately become prevalent in certain communities in this country, and while primarily an infection of adults, may affect babies in a maternity unit. The infection may attack breast-fed as readily as artificially-fed babies but is, as a rule, mild and the case mortality is low (Brown *et al.*, 1945).

(2) *Adverse environment.*—It is generally accepted that poor environment increases both morbidity and mortality from infantile enteritis. A few examples must suffice. Gastro-enteritis is predominantly a disease of poor-class urban areas. Thus, in the Royal Borough of Kensington, deaths from enteritis in 1933 were thirteen times more frequent in the poor northern district than in the wealthy southern area. Again, illegitimate infants deprived of parental care have a high mortality rate from gastro-enteritis, and in London the illegitimate child has a one in forty chance of dying from diarrhoea before it reaches its first birthday. Institutional care also increases the risk of diarrhoea, and the unique finding of a rising mortality rate from gastro-enteritis since 1930 in Greater London in contrast to other county boroughs may be related to the large numbers of infants admitted to hospitals and institutions in the London area. The increase in deaths from infantile enteritis in the war years and the occurrence of large-scale epidemics in some of our cities may be a reflex of the lower hygienic standards during the war.

(3) *The infant's defence against infection.*—The human infant must not be regarded as a miniature man. Its physiology is still immature and may be easily upset. For example, gastric acidity is low in the first few months of life and only reaches adult level by the end of the first year. Cow's milk curd is less easily digested than human milk and needs a greater amount of gastric juice. This fact, and the greater amount of base in cow's milk, may account for the alkaline reaction of the intestinal contents of the artificially-fed child. As a result the upper reaches of the gut may be colonized by coliform bacteria which in this way act as an irritant to the bowel. Further, toxic products of bacterial growth may be absorbed to the liver which often shows evidence of toxic damage in gastro-enteritis. Again, the infantile kidney has a poor excretory function, particularly for waste products and sodium. With excess fluid loss by the bowel, urea is retained in the tissue; oedema may follow, respiration is embarrassed, and anoxaemia may contribute to a fatal issue.

When infection occurs, the body tissues ordinarily react by an outpouring of phagocytes followed by the production of specific antibodies. The newborn infant with inadequate material in the shape of low plasma protein, poor plant in the form of an undeveloped lymphatic system, and unskilled workers stimulated by immature polymorphonuclear and monocytic cells, is ill-adapted to cope with bacterial invasion. The fraction of the plasma protein most important for defence against infection is the globulin in which antibody is contained, and it is known that the newborn lamb or calf, dependent on colostrum for its maternal antibody, has a low globulin content. The human infant, on the other hand, receives maternal antibody through the placenta, and should have adequate globulin at birth although there are but scanty data on this point. Its main

On the other hand these seasonal changes may be associated with a lack of vitamin D. It has been pointed out that sunlight during the summer and autumn may provide the calf born during the autumn with more vitamin D than the spring calf can obtain, and a lack of this vitamin may be as important as vitamin A. The seasonal changes may of course be associated with the character of the milk curd found in the stomach of the calf, and the milk of stall-fed cows is possibly not so easily dealt with by the calf as is milk from cows which have been at pasture.

Although white scours of calves is assumed to be one of the intestinal disorders of the newborn, it must be emphasized that most cases examined post-mortem show the presence of *Bact. coli* or some similar organism in the blood-stream. The disease is therefore a septicæmia and an antigenic substance obtained from strains of *Bact. coli* by chemical extraction is lethal to calves when given intravenously. This substance has been extracted from mucoid strains of *Bact. coli* and is capable of producing toxic symptoms in mice, manifested by diarrhœa and rapid breathing; a toxic effect can also be demonstrated in rabbits and in some cases is associated with diarrhœa. This substance will apparently induce the formation of antibodies to itself as shown by precipitation, but the serum antibody does not appear to be capable of protecting experimental animals from the toxic manifestation. A similar substance is also present in strains of *Proteus vulgaris* and *Ps. pyocyanea*. Although the work is very incomplete and no conclusions can be reached, it does serve to indicate that white scours of calves is not necessarily a specific intestinal disorder, but that the scouring is probably a manifestation of a general disease. Investigations of this kind may not explain or help towards a fuller understanding of the ætiology of white scours but will perhaps indicate the reasons why calves die when infection develops. It is of course possible that *Bact. coli* may not be of such importance as we believe, and it must be remembered that some of the early workers on lamb dysentery recovered *Bact. coli* from diseased lambs, and the significance of this organism was not clear at the time.

There are many gaps in our knowledge of these diseases of the newborn and those who have opportunities to observe the natural history of such diseases should note and record their observations. I believe that such an approach to the problems will give invaluable guidance and help to the experimentalist who is expected to solve problems and so often fails.

—, and HUGHES, D. L. (1935) *J. Comp. Path.*, **48**, 267.

Professor A. N. Worden referred briefly to certain as yet unpublished experiments on newborn calves which had been commenced during 1943 by F. Blakemore, T. Moore, himself and others at Cambridge (vide *Proc. R. Soc. Med.*, 1944, **37**, 446) and discussed them in relation to the earlier work of Theobald Smith, R. B. Little, Marion L. Orcutt, Paul Howe and their collaborators (*J. biol. Chem.*, 1921, **49**, 109 and 115; *J. exp. Med.*, 1922, **35**, 161; 1925, **41**, 81, 89 and 413) and to naturally occurring cases of disease in newborn calves. He still felt that experimental work on human cord bloods as reported by G. L. Boyd (*Canad. med. Ass. J.*, 1922, **12**, 274) and by J. H. Lewis and H. G. Wells (*J. Amer. med. Ass.*, 1922, **78**, 863) should be repeated with the aid of modern biochemical techniques.

Dr. R. L. Worrall agreed with Dr. Lovell that infectious diarrhœa of the newborn was a general disease. Enteritis was a misnomer, in view of the frequent absence of intestinal inflammation in infants dying from diarrhœa and vomiting. The disease was most prevalent in warmer weather and in hot climates. This would seem to suggest bacterial rather than virus causation if the infection was food- or water-borne. In attempting to distinguish particular strains of *B. coli* as possible infectious agents, bacteriophage typing rather than serological typing might prove more successful. Therapeutic administration of gamma globulin would be worth trying.

Dr. Robert Sutherland: It is perhaps unwise to apply the term *endogenous* to infections in the newborn infant, as this implies inevitability. The organisms concerned must have reached the infant from outside sources and an attempt should be made to limit the assaults made upon his imperfect antibody mechanism. The child probably has a high resistance to infections by organisms living in non-pathogenic association with his mother. The mother and her child should therefore be regarded as a mother-child unit and every care should be taken to protect the infant from organisms from other sources. We must also try to improve the newborn infant's resistance to infection. It may be that a general improvement in the health and nutrition of pregnant women would lead to improved powers of phagocytosis and antibody formation in their infants. It would be interesting to get a comparative study of these powers in infants born to women in income-groups I and V.

which appear to be less greedy; and this is bound up with an abundance of milk in the ewe and this in turn is influenced by the good condition of the grass. Handling of lambs by the shepherds no doubt helps to spread the disease in infected areas and the suckling of lambs by ewes which have lost their own has a similar influence. The breed of sheep is also of importance and cross-bred lambs are apparently less susceptible than some of the pure-bred ones.

These well-known observations are worth considering when discussing similar conditions of the newborn, the ætiology of which is still far from clear.

White scours in calves.—This is considered to be one of the common diseases of calves and attacks them within a few hours or days of birth. It has a seasonal variation, there being a higher mortality in calves born in the spring than those born in the autumn, and is in most cases associated with invasion of the blood-stream by *Bact. coli* special virulent strains of which exist; predisposing causes are, however, apparently necessary. It is difficult to estimate how common this disease is but a survey made in 1936-37 showed that in well-managed herds in this country there is a death-rate in calves of about 5.5% (Lovell and Hill, 1940). If we accept as a rough estimate that there are in England and Wales three million cows and heifers in milk, cows in calf but not in milk, and heifers in calf, and if we assume that the birth-rate is two thirds of this, then some two million calves are born in England and Wales per year. The number which die will be at least 110,000 and it was shown some years ago (Lovell and Hughes, 1935) that 37 of 100 calves which died succumbed to white scours. A simple calculation based on these figures shows that there is an annual loss of over 40,000 calves from white scours in England and Wales. Although this is a high figure it is probably a conservative estimate.

Bact. coli is accepted as the common organism associated with this disease in calves, and the predisposing causes are probably associated with inadequate digestive functions, lack of colostrum or over-distension of the digestive tract. Colostrum supplies the calf with certain proteins—globulins—and there is a relationship between the accumulation of globulins and the appearance of antibodies in the blood of calves following the feeding of colostrum. It is clear that colostrum has at least one function, which is to provide calves with antibodies against prevalent bacteria which are harmless to them in later life. These antibodies are in a higher concentration in the colostrum than in the serum and the intestinal wall of the newborn calf is permeable to these antibodies for the first two to three days of its life. It has been shown by American workers that a protective meal of serum from a cow in the same environment will also protect calves but apparently less effectively than colostrum. On the other hand some observers suggest that colostrum acts because of its vitamin content and that calves born of mothers with a low content of vitamin A in the colostrum are more liable to infections such as white scours than calves born of mothers whose colostrum has a higher vitamin A content. Attempts have been made to influence the incidence of white scours by giving vitamin A concentrates at birth. Attention has also been paid to other vitamins, for the synthesis of the B complex may be inadequate in the newborn calf; where colostrum is likely to be deficient or where scouring exists, the giving of shark-liver oil and capsules containing one or more of the B group of vitamins has been recommended.

No one doubts the value of colostrum to the newborn but wherein does this value lie? Is it the antibody content? It may be, but it may be that the vitamins or even the protein which colostrum supplies help the calf in its resistance to disease.

There is undoubtedly a delicate balance existing between *Bact. coli* and the intestinal tract of calves and although the lack or deficiency of colostrum may be one of the causes which upset that balance in favour of the bacteria, the intestinal disturbance may be induced by infrequent feeding or feeding too much at a time. It is generally conceded that suckled calves do better than bucket-fed ones and losses are negligible in calves suckled on nurse cows for the first month or so of life. Preventive measures and investigation should therefore be directed also towards the general conditions under which calves are born and reared. This implies the paying of attention to the mother, for the seasonal swing in mortality of calves has been linked up with the diet of the mother during the later days of pregnancy. It has been concluded that as the cow stores vitamin A while at pasture and loses it during the winter, then a winter pregnancy is followed by a low vitamin A content of the colostrum in the spring months of the year. Attempts have been made to increase the vitamin A content of colostrum by feeding carrots and cod-liver oil to cows during the later months of pregnancy and suggestions have been made that cows should be allowed a non-lactating period of not less than three months in order to ensure a high vitamin A content of the colostrum. It must be remembered that cows are expected to secrete enormous quantities of milk and to nourish a fœtus at the same time; good calf husbandry must therefore be linked with care of the mother during pregnancy.

Section of Anæsthetics

President—GEORGE EDWARDS, M.R.C.S., D.A.

[February 1, 1946]

DISCUSSION ON ANÆSTHETICS IN TROPICAL CLIMATES

Dr. H. K. Ashworth: The title "tropical climates" does not imply conditions of heat limited only to the geographical boundaries of the tropics. Many parts of the world outside these geographical limits provide similar climatic problems for the anæsthetist. In addition there is another factor besides that of heat, namely the effect of high altitudes on the administration of anæsthesia. The ideal remedy for the majority of climatic difficulties in the tropics is, of course, a properly air-conditioned operation theatre block, including resuscitation and recovery rooms, and efficient cold storage for drugs. The use of an air-conditioned operation theatre block has been criticized on the grounds that the eventual transfer of the patient to less temperate conditions is prone to increase the incidence of post-operative pulmonary complications. Unfortunately, no comparative figures are available from which to draw an accurate conclusion as to the validity of this criticism. What is certain, however, is that the pulmonary morbidity would require to be a big factor to outweigh the proven advantages of air-conditioning, which are as follows:

- (1) Avoidance of dehydration of the patient by minimizing the otherwise excessive sweating during anæsthesia.
- (2) Minimization of the excessive heat factor which often predisposes to the development of ether convulsions.
- (3) Provision of less exhausting conditions for the operation theatre personnel.
- (4) Provision of fly-proof and dust-proof conditions in the operation theatre.

Air-conditioned theatre blocks are unfortunately expensive to erect and maintain and although the ideal, one is unable to visualize their installation in the immediate future in more than a small percentage of the total number of operation theatres in the tropics. This being the case, it is necessary to consider the effects of lack of air-conditioning on anæsthesia in hot climates.

Equipment and drugs.—(1) Whatever apparatus is used, the more vulnerable parts should be duplicated. The best machine is useless if it has to stand idle while a replacement is obtained from England. A water sight-feed Boyle's apparatus may not enable the anæsthetist to command the full range of inhalational anæsthesia, but at least it has the advantage of relative invulnerability to rough handling by native theatre orderlies and ease of repair in case of damage.

(2) If CO₂ absorption is used, it is recommended that the apparatus should be fitted with a circle rather than a "to and fro" absorber, as it was found that a canister at the face-piece soon became unpleasantly hot, and it was felt that such a state of affairs, if prolonged, would be detrimental to the patient.

Hot, dry climates provide the optimum conditions for the accumulation of static electricity and the usual precautions as to earthing of apparatus, moistening of rubber parts, avoidance of friction, and of short-circuits of electrical instruments are absolutely essential in such climates.

Medical gas cylinders may only be filled to 90% of their normal stated capacity in British tropical possessions. Ether should be supplied in tins and not in bottles—the waste by evaporation even from unopened bottles was colossal.

One frequently heard that it was impossible to induce or to keep a patient sufficiently anæsthetized with open ether in hot climates, but this was soon disproved.

Dr. Cruickshank has shown conclusively the vital importance of breast-feeding. Our complacent acceptance of artificial feeding in 80% to 90% of 1-month old babies and 50% of 4-month old babies is something of which we should be ashamed. Doctors and nurses must realize their grave responsibility in this matter. We should feel that it is a reflection upon us if a baby in our charge is deprived of these advantages. Tied up with this, it is essential that doctors and nurses should learn more about the difficulties of breast-feeding and how to deal with them. Failure to insist upon the continuation of breast-feeding is often due to lack of knowledge of how to make it possible; recourse to artificial feeding is the easiest way out of a difficult situation. The better education of the profession in the problems of infant feeding and handling is therefore an essential corollary to a public campaign in favour of breast-feeding.

Dr. M. Dynski-Klein endorsed Dr. Cruickshank's views on the potential pathogenic importance of endogenous *Bact. coli* in the genesis of intestinal disorders of the newborn. Clinical studies carried out in the University Children's Clinic in Prague (Profs. Fischl, Epstein) in order to determine the nutritive value of expressed breast-milk showed that 50% of babies fed this milk did not develop the Gram-positive (*Lacto bacillus bifidus*) flora ("Blue bacillosis") of the breast-fed infant, but instead showed the Gram-negative coli flora ("Red bacillosis") found in artificially-fed infants. Changes in the pH of the faeces preceded the appearance of *Bact. coli*. Infants fed the expressed breast-milk developing a *Bact. coli* flora failed to thrive and sooner or later showed gastro-intestinal disturbances of varying severity. Feeding sterilized breast-milk gave the same result. Addition of carbohydrates not readily fermented, such as rusk flour or 5% to 7% rice gruel, to expressed breast-milk favoured development of the bifidus flora and once this had been established the infants started to gain weight and gastro-intestinal symptoms disappeared. It thus seems clear that, in addition to exogenous infection, gastro-intestinal disorders may be brought about by any diet favouring the growth of *Bact. coli*. This may be caused by changes in the composition of the intestinal chymus. Breast-feeding is thus the strongest weapon in the prophylaxis of gastro-enteritis in the newborn and repeated outbreaks of this disease in the Maternity Department of the West Middlesex County Hospital have been successfully controlled by raising the rate of breast-feeding to 98%. The amount of diphtheria antibody transmitted through breast-feeding is insignificant and active immunization of mothers is thus of no value for passive immunization of infants against disease.

References.—BESSAU (1938) *Acta Paediatr.*, 16, 299. CATEL, W. (1938) *Med. Klinik.*, 34, 215. EPSTEIN, B. (1938) *Acta Paediatr.*, 16, 521. FISCHL, R. (1922) *Deutsche Naturforschertagung.* Leipzig.

Mr. M. Crawford said that Dr. Cruickshank had alluded to the possibility of a virus being concerned in the aetiology of gastro-enteritis and had asked if any member with veterinary experience had any knowledge of the behaviour of the foot-and-mouth disease viruses in young calves. He had seen many outbreaks of foot-and-mouth disease in dairy herds in Ceylon, a country in which the slaughter policy was not enforced. A feature of these outbreaks had been a number of sudden deaths in young suckling calves. These had not shown the usual symptoms and lesions of foot-and-mouth disease. Calves, to all appearances healthy, cried out, fell to the ground, struggled violently for a short time and died. On post-mortem examination a most intense reddening of the gastric (4th stomach) and intestinal mucous membranes was present. The appearances resembled that seen in acute irritant poisoning such as acute arsenical poisoning. Such deaths occurred only at times when foot-and-mouth disease was rife in the herd. Another virus disease which Mr. Crawford had observed in calves was cowpox. That disease occurred frequently in Ceylon in milch cows. Calves suckling infected cows usually developed pock lesions in the mouth, the lesions being surrounded by a generalized inflammation of the buccal mucous membrane. They lost condition and suffered from diarrhoea. It was not possible to say whether lesions of gastro-enteritis were present or not as opportunity for post-mortem examination had not occurred.

Dr. Martin Bodian discussed the incidence of positive blood cultures mentioned by previous speakers in connection with gastro-enteritis in newborn human beings and animals—one speaker had even mentioned four blood cultures taken on successive days from a sheep, and positive for four different organisms.

Dr. Bodian drew attention to his own early results in neonates with a fair number of strains of *Staphylococcus albus*, *B. coli*, &c., isolated from the blood-stream, until he adopted a complete non-touch technique for taking blood cultures from the internal jugular vein. The incidence of contaminants was subsequently nil.

He also warned against any attempt to link up any agonal or post-mortem blood cultures positive for *B. coli* with the aetiology of gastro-enteritis, since it is well known that such terminal invasion of the blood-stream by intestinal organisms takes place in many other conditions.

Dr. R. E. Pleasance: *Intravenous anæsthesia in the tropics.*—At the Base Hospital, where I was stationed in India, for a period of two and a half years, intravenous anæsthesia was extensively used. Out of a total of nearly 8,000 anæsthetics, no fewer than 4,000 were intravenous anæsthesias, in some form or other.

In the early stages 91% were given intravenous anæsthesia without combination with any other form of anæsthetic agent. Later, however, this figure was reduced to 40% owing to the need for additional anæsthesia for the more difficult case.

In June 1942 only 24.8% of all cases were given intravenous anæsthesia, but this figure steadily increased, as supplies improved, until in the six months ending December 31, 1944, no fewer than 64.75% of all cases were so anæsthetized.

Preparation of the solution.—Whenever possible the solution was prepared at least twenty minutes before it was required for injection. For ordinary routine short cases a 5% solution was used. This was prepared in the usual manner, 20 c.c. of distilled water being added to the ampoule containing 1 gramme of pentothal sodium. Cases requiring prolonged anæsthesia, except for the initial injection for induction purposes, a 2½% solution.

Cases were divided into those requiring a short anæsthesia and those requiring a long anæsthesia.

The first group were anæsthetized without premedication, as a result of which unconsciousness was not unduly prolonged, and the reflexes were depressed for a short period only, a very important factor where the nursing staff is not too plentiful.

The second group were premedicated with morphine ¼ grain and atropine 1/100 grain, or 1/150 grain for preference, or occasionally with scopolamine 1/100 grain, at least 1½ hours before operation.

Technique of administration.—Four main principles were maintained: (1) That the case was suitable for this type of anæsthesia. (2) That the injection was given slowly and intermittently. (3) Oxygen in adequate supply, and provision for a free airway was at hand. (4) Provision was made for relieving respiratory or cardiac failure.

Five types of cases were dealt with: (1) The simple routine case of short duration. (2) General surgery requiring prolonged anæsthesia. (3) Plastic surgery. (4) Neurosurgery. (5) Thoracic surgery.

Results.—In 4,000 cases there were no deaths, either immediately or remotely connected with this form of anæsthesia. Complications were rare.

Three cases only of venous thrombosis were observed. One after the injection of a 5% solution. A second injection at a later date had no ill-effects. A second case was after the injection of a 2½% solution, and the area where the thrombosis occurred was remote from the site of the injection. The third occurred in a dental surgeon, who had to have a simple whitlow opened. The amount of pentothal used was small, and the operation of short duration.

One case of headache, lasting twelve hours, was recorded.

A number of patients suffering from malaria required operation. These all reacted normally, except that they were found to require less pentothal than the usual patient.

Several developed high temperatures immediately after operation under pentothal. An examination of the blood disclosed the presence of the malarial parasite. All did well and were not adversely affected by the intravenous anæsthesia.

Numerous patients who were having large doses of sulphanilamides were also given intravenous anæsthesia without any subsequent trouble developing.

Several patients with a history of asthma were given pentothal. One for the removal of a foreign body from the lung gave a long history of attacks. In no case was any ill-effect observed.

One case appears of sufficient interest to record.

A soldier, who had been thrown out of an Army truck, pitched on his head, and was brought into hospital unconscious. Colour deeply cyanosed. The only respiratory movement to be observed was that of the diaphragm. At the request of the surgeon "a spot of pentothal" was given to reduce a severe compression fracture of his cervical vertebra. I gave slowly 6 c.c. of a 2½% pentothal solution. The movement of his diaphragm immediately ceased. After the usual period it began to move again, and the operation of reduction was performed.

Comments.—In the tropics, where liver deficiency is likely to occur, due to the various causes so readily obtainable in such a climate, the anæsthetist must be constantly on his guard against the administration of an overdose of pentothal sodium. Especially is this the case with the Indian who requires 30% to 40% less pentothal, as a general rule, than the European.

At the same time the British Other Rank in the tropics requires about 20% less pentothal for a given operation than his fellow in this country.

Atropine should be avoided as a premedicant. Omnopon and scopolamine, or, if not available, morphia and hyoscine, were widely used for this purpose. In addition to being sedative, it was felt that these drugs were less likely to cause disturbance of the heat-regulating mechanism, and thus to diminish another possible factor in the cause of ether-convulsions. As an additional precautionary measure against the occurrence of hyperpyrexia during anaesthesia and operation, mackintosh sheets should not be used to cover the patient. The part played by the skin in regulating body temperature is supremely important in hot climates.

Local and spinal anaesthesia were both used. Hot and dusty climates make it even more necessary to ensure the strictest personal attention to the sterilization of syringes and needles and the use of a rigorous aseptic technique of administration.

Pentothal was, of course, by far the commonest anaesthetic agent used by the Army in the Far East—particularly for battle casualties.

The effect of high altitudes on the administration of anaesthesia.—The barometric pressure at 6,000 feet is 600 mm.Hg or a reduction of slightly more than 20% compared with the pressure at sea-level, and it does have a practical bearing on the administration of gaseous anaesthetics at high altitudes for it means that the pressure of oxygen or of any inspired gas is reduced by the same percentage unless it is administered under pressure. Unless pressure is used it is extremely difficult to produce and maintain anaesthesia with nitrous oxide and oxygen.

Additional oxygen should be given freely with any form of anaesthesia which impairs the normal defence mechanism of hyperpnœa in response to anoxia at high altitudes. The necessity to supply oxygen is not confined only to the administration of inhalational anaesthetics and it should be an invariable accompaniment of intravenous and high spinal anaesthesia in such conditions. The blood picture of people who live for any length of time at high altitudes undergoes a change which affects the administration of anaesthetics.

The patient.—In hot climates the most important thing is to ensure that the sick patient is adequately hydrated. A healthy adult in the tropics loses between 1 and 1½ gallons of fluid per day, even when sedentary. The greater proportion of this is lost from the skin. If the metabolism is raised by fever this loss is greatly increased, and the wise anaesthetist will ensure that the fluid intake of the patient for the twelve hours previous to operation is accurately measured. In cases in which oral intake of fluid is contra-indicated, the pre-operative installation of an intravenous drip is an absolute necessity. Brigadier H. L. Marriott (1945, *Lancet* (i), 679) has stressed elsewhere the necessity also to ensure that the patient has an adequate amount of salt, and he has shown that most forms of heat exhaustion are due to an insufficiency of salt. For this reason, all fluid intake during the twelve hours previous to operation should be salted. A teaspoonful of salt dissolved in 2 pints of lemonade is almost undetectable.

Tropical diseases in relation to anaesthesia.—Malaria is still by far the commonest tropical disease and one with which the anaesthetist is particularly concerned owing to the liability of an injury to precipitate an acute attack of the disease in an already malarious subject. Cases were recorded in which malaria began at the time of operation and the patient had a rigor and presented a clinical picture of malaria during his recovery from anaesthesia. In the difficult days of campaigning on the Burma border in 1942, in one Mobile Surgical Unit, the coincidence of malaria with anaesthesia and operation was so great that quinine, 6½ grains, were added to the pre-operative drip as a routine. There is, however, another undesirable complication of malaria, namely that it engenders in the patient extreme susceptibility to small doses of pentothal. Amoebic dysentery is the other common tropical disease which complicates anaesthesia. In addition to the anaemia, here again there is a liability to impairment of liver function with the consequent need for caution in the exhibition of intravenous barbiturates.

Racial difference.—My personal experience of anaesthetizing natives was extremely limited but the general conclusion with regard to the majority of Indians was that they are more susceptible to intravenous barbiturates and that their blood-pressures tended to be lower than those of Europeans. It was reported that West African natives were sometimes excited rather than sedated by omnopon and scopolamine.

Psychological.—The induction of basal narcosis by means of pentothal is of enormous psychological value among uneducated natives. The fear of mutilation when unconscious is based on religious beliefs and is often a very potent factor if attempts are made to induce anaesthesia by inhalational methods in a conscious patient. This results in determined resistance and prolonged struggling, with their accompanying anxieties for the anaesthetist.

hepatitis. In each case the amount of barbiturate used intravenously must be kept at a minimum.

Indian patients.—(1) The Indian is usually under weight and therefore takes less anæsthetic than the European. This also applies to the amount of sedative necessary for premedication.

(ii) The blood-count is usually low so that adequate oxygen must be given to him. It should be remembered that for major operations a lower pre-operative Hb. may be regarded as more normal than in the European. My old friend and colleague, the late Colonel S. N. Hayes, who had an extensive experience in performing hysterectomies in the Punjab, did not give his patients a pre-operative blood transfusion unless their Hb. was below 35%.

(iii) The Indian usually has a low blood-pressure so that it is reasonable to regard a systolic blood-pressure of 90 mm.Hg as one high enough to proceed to operation instead of 100 mm.Hg as in the European.

(iv) He is more prone to lie motionless and listless after operation than the European, so that it is more essential to make him adhere to the "hourly stir-up" in order to prevent post-anæsthetic chest complications.

(v) The Indian has short air passages, for a tube that has been correctly measured, i.e. twice the distance from the pinna of the ear to the nares, if passed through the nose would, in many cases, enter the right bronchus. Therefore a correspondingly shorter tube is needed for the Indian both for nasal and oral intubation.

(vi) He is an unsuitable patient for local or spinal analgesia unless extremely carefully premedicated. I make this statement in spite of the frequency of spinals and locals in Indian operating theatres—but frequently in that country the operating theatre is not a happy place. Due to the scarcity of trained anæsthetists these methods are safer than the use of inhalation methods, usually chloroform, by the inexpert. The uneducated Indian, like the uneducated throughout the world, is unable to differentiate between touch, pressure and pain. This fact was demonstrated strikingly when I had an opportunity of doing caudals for a number of Cæsarian sections for Indian women. Often the patient would be quite silent until the cry of the infant was heard, then she would shriek violently, for she had realized that she had had a baby and ought to shriek with pain!

Naturally most of my remarks do not apply to those who live completely European lives, for just as we have our problems—the bookmaker and the brewer's drayman for instance—so has India its non-teetotal Sikh!

Dr. Bernard R. M. Johnson: *Anæsthetics in tropical climates.*—The condition of "Heat Hyperpyrexia" is so insidious in its onset and of such a lethal character that it demands the special attention of the anæsthetist practising in the tropics. When it occurs, treatment must be urgent and drastic. All other considerations, either surgical or anti-malarial, must take second place, or the patient will rapidly be lost. The only real remedy lies in prevention, and this can only be attained by training of the nursing staff. They should, in my opinion, be taught to expect the condition to arise in every post-operative case and should live in constant fear of it. European standards of post-operative treatment, with regard to protection from cold, are not easily abolished in the routine of well-trained nursing staffs. Patients should lie post-operatively, wearing only a thin linen cover over the lower part of the body, and a rectal temperature should be taken half-hourly. A steadily rising temperature should demand immediate treatment, i.e. cold sponging, fanning, &c. This record of the body temperature must be charted, and not left to memory and should be continued until consciousness is fully recovered.

Large parts of the tropics, even in peacetime, have very uncertain and unreliable communications—this being so, all outlying districts should be in possession of an Oxford Vaporizer, since supplies of nitrous oxide, cyclopropane, &c., may easily fail, and owing to the humidity of the atmosphere, it is impossible, or almost impossible, to administer open ether.

It was found, not only in Nigeria but in the climate of North Africa and Southern Italy, that it was not necessary to put any water in the water jacket of the Oxford Vaporizer and that, on hot days, it was apparent that a higher percentage of ether was being delivered by the machine than the indicator would lead one to suppose.

More caution than usual should be taken when using the barbiturates in cases of chronic malaria, or in those who have recently suffered from hepatic diseases, when associated with prolonged suppuration. This opinion is based on purely clinical observations as, unfortunately, proper scientific investigation was, for many reasons, not possible.

Dr. Victor Goldman: *Anæsthesia in the tropics.*—The important considerations in discussing anæsthetics in tropical climates may be grouped under the following five headings: (1) Agents and apparatus. (2) Premedication. (3) Fluid loss. (4) Hill stations. (5) Patients—(a) European, (b) Indian.

(1) *Agents and apparatus.*—In tropical climates unless the theatre is air-conditioned, inhalation anæsthetics are rendered difficult on account of rapid vaporization. It used to be said that tough individuals could not be taken to a deep plane of anæsthesia by means of open ether and for that reason chloroform used to be the routine anæsthetic. However, if care is taken ether may be used with success. Ether containers, which should be tins rather than bottles, should be kept in a refrigerator or an ice-chest before opening and the container when in use wrapped up in a damp towel so that evaporation will help to prevent the ether from boiling. A gamgee pad is used on the face and the usual mask with about 12 layers of gauze. This mask is then covered by a second gamgee pad which should not have a hole in it. Ether is dropped on to the outer surface of the top gamgee pad, which is then turned over, and further ether added as required—after each addition of ether the gamgee pad is turned over. Actually induction is rapid in a hot theatre as ether vaporizes so rapidly.

Some experts prefer an inhaler such as a Clover or a Hewitt, but I do not like them unless the bag is dispensed with, owing to the tendency to high concentrations of carbon dioxide that may result. The Oxford Vaporizer is by far the best apparatus for giving ether in the tropics, but if the temperature of the theatre is over 85° F., ice cold water must be placed in the vaporizer instead of hot water.

Ether may be added to gas and oxygen mixtures from a Boyle or similar apparatus without difficulty, and if a closed circuit is employed the canister should be kept in a cool place between cases. To and fro canisters placed near the mask may become overheated. If this happens the canister should be changed or the method discontinued, though an ice-bag wrapped round it will often prevent this eventuality. Chloroform, if used, should be *undiluted with ether*, as mixtures never vaporize in constant percentages.

(2) *Premedication.*—Atropine prevents the normal mechanism of heat regulation by disturbing the action of the sweat glands; for this reason it should never be given to patients before operation in hot theatres. Hyoscine produces the same drying of the secretions of the respiratory tract without the same upset of the heat-regulating mechanism. The combination of morphia and hyoscine was the usual premedication for adults and in children we soon found that small doses of hyoscine were much better than the routine atropine.

If the theatre is air-conditioned the temperature should not be too low, in fact the optimum temperature was found to be 80° F. An important point is that if the patient is not residing in an air-conditioned ward, he should be brought down to the theatre suite at least half an hour before the commencement of the anæsthetic so that his heat-regulating mechanism can become readjusted before he is rendered unconscious.

(3) *Fluid loss.*—Dehydration must be prevented at all costs as fluid loss is considerable for, following the administration of premedication, the patient is not able to drink copiously until he has completely recovered from the anæsthetic. For this reason all patients undergoing an operation which will last for an hour or more should be given an infusion of intravenous saline, and at least a pint an hour can be safely administered. In this connexion it should be stressed that the habit of covering any part of the patient's body with waterproof sheeting must be absolutely prohibited in the tropics.

(4) *Hill stations.*—By the term Hill Stations I mean those that are over 5,000 ft. above sea level, and above those heights it is known that the partial pressure of oxygen in the air is appreciably lowered so that on first arrival in such a station one finds difficulty in walking fast or in climbing hills. After about five or six days there is a physiological increase in the blood-count and effort produces less embarrassment. It was quite common in Murrec, which is 7,000 ft. above sea-level, to get normal counts of 6½ million red cells after a week at that height. For this reason only urgent cases should be anesthetized in such stations unless they have had time to become acclimatized. Even in the acclimatized patient under deep anæsthesia it will be necessary to give additional oxygen under open ether or if the Oxford Vaporizer is employed. This precaution is always necessary during continuous pentothal anæsthetics and high spinals at such altitudes.

(5) *European patients.*—The European tends to take more liquid refreshment in the tropics and is therefore more resistant. He must be allowed to take his usual ration both before and after the anæsthetic. We must always be prepared for the patient who has recently had a course of anti-malarial treatment or who has had an attack of

American anæsthesiologists, but one has gained the impression that they have not fully appreciated its full field of usage nor its importance to the patient.

J. Halton first used d-tubocurarine chloride in November 1944 in an attempt to overcome the disadvantages of the barbiturates consequent on their use as the sole agent to produce anæsthesia in thoracic operations, but it was not until April of last year with the advent of regular supplies that we began to realize its great possibilities. Intocostin was tried, but it seemed to be unreliable in potency, perhaps due to the instability of the solution, and no definite results could be forecast with the samples that we employed. As a result, we returned to the crystalline extract, d-tubocurarine chloride, prepared by Burroughs Wellcome & Co. This has proved of constant potency and very satisfactory.

Pharmacology.—Pharmacologically, the exact nature of the drug is wrapped in much the same mystery as the preparation of the crude poison. The crude extracts are obtained from various vines and plants, and the very nomenclature used to describe these extracts is an indication of our ignorance. Thus that variety delivered to the importers in gourds has been known as "Calabash" or "Gourd" curare, that delivered in earthenware pots as "Pot" curare, and that in bamboo tubes "Tube" curare. This latter is a brown or black shiny resinoid mass, and it is from this variety that the crystalline extract "d-Tubocurarine Chloride" is obtained. Table I shows the alkaloids that have been isolated from the crude extracts.

TABLE I

Tube curare	—————→	Tubocurarine	—————→	Tubocurarine chloride ($C_{25}H_{41}O_4N_2Cl \cdot 2H_2O$)	
	—————→		—————→	Curine ($C_{24}H_{35}O_4N_2$)	Weaker in action. Toxic to heart.
Calabash curare	—————→		—————→	Curarine ($C_{18}H_{24}O_4N_2$)	Extremely potent. Similar effects to tubocurarine. Related to strychnine.
	—————→		—————→	Protocurine ($C_{20}H_{23}O_3N$)	
Pot curare	—————→		—————→	Protocuridine ($C_{24}H_{33}O_4N_2$)	
	—————→		—————→	Protocurarine ($C_{18}H_{23}O_3N$)	Only one giving curare action.

Physiology.—Curare has no action when taken by mouth, hence the perfect safety of the native when he ate his victim after a day's hunting. This immunity is due to detoxication by the liver and not to destruction by the digestive juices. It must be injected either subcutaneously or intravenously. Subcutaneously administered, its action appears in about twenty minutes, but intravenously the action commences within ten seconds, and takes three to four minutes to reach a maximum.

Having entered the circulation it is in part changed by the liver and in part excreted via the kidneys unchanged (Boehm, 1920). It may be noted, in passing, that in the presence of renal damage of any consequence an otherwise safe dose may well cause considerable embarrassment.

It is necessary for a moment to consider the action of curare on (a) the neuromuscular mechanism, and (b) the nervous system.

(a) Claude Bernard (1840), in his classical experiments on frogs, showed that curare produced paralysis of voluntary muscle by an interference with the nerve impulse at the neuromuscular junction. In the curarinized animal both the nerve and muscle are still capable of responding to stimuli, but the break occurs at the junction of the two.

The work of Dale, Feldburg and Vogt (1936), and Brown (1937) and others, leads us to believe that on stimulation of a nerve to voluntary muscle, acetylcholine is produced at the neuromuscular junction, and that curare produces its paralyzing effect by preventing the action of this on the receptor substance of the muscle.

While on this subject it is useful to consider the action of physostigmine which is said to be the natural and physiological antidote to curare.

Normally, acetylcholine is neutralized by an enzyme, cholinesterase, present in the tissues. Physostigmine prevents this neutralization, and so allows an abnormal and excessive barrage of acetylcholine to play on the receptor substance; this may succeed in overcoming its inhibition by curare.

In this series physostigmine has been used on two occasions, and we were not impressed by its action. However, many workers have reported dramatic results, and this is a substance that should always be at hand when and wherever curare is being used.

Mention must also be made of the effect of the climate on the anaesthetist and his assistants. After prolonged exposure to high temperatures and high humidity, even the best men showed a loss of interest and keenness in their work and a tendency to general lethargy.

Major R. P. Harbord asked what was the evidence for the statement that atropine disturbs the heat regulating mechanism more than hyoscine?

Cases coming to operation in the forward areas with malaria were uncommon during the campaigns about the Mediterranean.

Pentothal had been a useful anaesthetic for maxillo-facial surgery in some cases for it shortened the period before intubation and minimized aspiration.

Dr. V. Goldman, in reply to Major Harbord, said that although atropine and hyoscine are close chemical relatives, they produce some different effects when administered. The effects of atropine tend to be excitant, those of hyoscine depressant. Apart therefore from their similar drying effect on mucous membranes, atropine is an opponent of anaesthesia, whereas hyoscine is an adjuvant. Adriani states that the temperature regulating centre is stimulated by large doses of atropine¹; and it is well known that atropine increases the basal metabolic rate.

Dr. G. S. W. Organe asked Dr. Pleasance whether in view of the extremely low incidence of thrombosis he had found after pentothal all patients had been examined with this possibility in view or whether these were merely the cases in which symptoms had presented.

Dr. R. E. Pleasance replied that, as far as was possible, all patients had been examined with this possibility in view.

[March 1, 1946]

A Milestone in Anaesthesia?

(d-Tubocurarine Chloride)

By T. CECIL GRAY, M.B., Ch.B., D.A., and JOHN HALTON, M.B., Ch.B.

History.—Curare, the South American arrow poison, has been known since Hakluyt published his account of Sir Walter Raleigh's voyage up the Amazon in 1595.

The exact origin of this "flying death" is still veiled in mystery. Its actual preparation is surrounded by all the esoteric magic and superstition of these strange people descended from the Aztecs, and very little more is known about it now than was discovered by Charles Waterton, a traveller of Lancashire origin, in his journey to the wilds of Demerara in 1812—a journey undertaken with the special object of investigating the origin and preparation of the Wourali poison.

This explorer wrote a book "Wanderings in South America" in 1812, and the description therein of the distillation of the arrow poison from the vine Wourali, the addition of sundry noxious substances, including Indian pepper and the pounded fangs of the Labarri snake, is well worth reading. He tells most vividly of the effects of the poison on various animals. In 1840, Claude Bernard confirmed the observations of Waterton, and attributed the effects of the poison to paralysis due to interruption of the neuromuscular conducting mechanism.

In 1935, Harold King gave the name d-tubocurarine to an alkaloid isolated from tube curare, but little was known until in 1938 Richard Gill (1940), who lived for many years among the Amazons and in the jungles of Ecuador, brought to the United States samples of raw material and of the various plants used in its preparation, and Professor McIntyre (1943) of the University of Nebraska, together with the firm of manufacturing chemists "Squibbs," prepared an extract of standard potency which they labelled "Intocostarin".

In this country, curare was first used by Cole in 1934, Mitchell in 1935, and Ranyard West in 1936, all of whom used it in the treatment of tetanus.

In 1940, Bennett, of Nebraska, described the prevention of trauma during convulsive therapy by the intravenous injection of intocostarin.

In January 1942 Griffith (1944) first used the drug as an aid to anaesthesia in the Homœopathic Hospital of Montreal. It is interesting to note that up to April 1945 Griffith (1945) had only used intocostarin in 300 cases. Since then there has been a flux of articles from

In clinical dosage, little or no effect can be observed on the blood-pressure. Depression may be observed when a large dose of curare is injected quickly, especially if in association with a barbiturate (fig. 2).

Conversely, a slight rise has been occasionally noted (fig. 3), a fact that may be accounted for by the quixotic action of curare on the autonomic nervous system, or in some cases by inadequate ventilation of the lungs with consequent accumulation of carbon dioxide.

FIG. 2.—Blood-pressure, pulse and respiration in male patient aged 49, undergoing cholecystectomy, with continuous pentothal and curare anæsthesia. (Note initial depression of systolic pressure.)

FIG. 3.—Blood-pressure, pulse and respiration in a male patient aged 48, undergoing a partial gastrectomy under pentothal and curare anæsthesia. (Note (i) initial rise in blood-pressure, and (ii) perfect stabilization during the last hour.)

The amazing effect of the arrow poison when injected into an animal has been most beautifully described by Waterton and is worthy of quotation:

"Having procured a healthy full-grown fowl, a short piece of poisoned blow-pipe arrow was broken off and run up into its thigh, as near as possible betwixt the skin and the flesh, in order that it might not be incommoded by the wound. For the first minute it walked about, but walked very slowly, and did not appear the least agitated. During the second minute it stood still, and began to peck the ground; and ere half another had elapsed it frequently opened and shut its mouth. The tail had now dropped and the wings almost touched the ground. By the termination of the third minute it had sat down, scarce able to support its head, which nodded, and then recovered itself, and then nodded again, lower and lower every time, like that of a weary traveller slumbering in an erect position, the eyes alternately open and shut. The fourth minute brought on convulsions, and life and the fifth terminated together."

In the conscious human subject the muscles of the eyes, mouth and fingers are affected first, then those of the trunk and limbs, and finally the diaphragm. Consciousness is retained, and recovery occurs in the reverse order, being complete in about thirty minutes from a single injection. American workers (Whitacre and Fisher, 1945) have actually pushed the drug beyond the stage of diaphragmatic paralysis, and obtained unconsciousness. This seems to us a completely unjustifiable procedure, and the narcosis may well have been due to anoxia, although curare may have some action on the synapses of the central nervous system, in view of the fact that there is some evidence that here too acetylcholine plays some part in impulse transmission.

Technique.—The tubocurarine when first received must be sterilized. It has been our custom to autoclave the dry powder at 10 lb. pressure for thirty minutes, and cultures taken from the solution have proved sterile. Moisture must not be allowed to enter the phial during autoclaving as the powder becomes discoloured and presumably unfit for use.

After the usual premedication, in our cases morphia 1/6 grain and atropine 1/150 grain to 1/100 grain, anæsthesia is induced with whatever may be the agent of choice.

The curare, not itself an anæsthetic, is used as an adjuvant in order to obtain good relaxation at any time and in a very light plane. It is injected as and when required, allowing the requisite three to four minutes for it to take effect.

Three main techniques have been employed:

(1) The single dose method, for the induction of anæsthesia, short operations and endoscopies, oral and anal.

Employed in this way a mixture of 15 mg. of tubocurarine with 0.5 gramme of pentothal is injected fairly rapidly. After two or three minutes respiration becomes very shallow or ceases altogether, the jaw is completely relaxed and there is no spasm or cough when an airway is inserted or an endotracheal tube is passed. Furthermore, the

That, briefly, is how curare produces its relaxation, which makes it of such great value to the anaesthetist.

(b) *The effect of curare on the nervous system.*—Acetylcholine appears to perform some function in the transmission of nerve impulses through the ganglia of the autonomic system, and possibly also through all the synapses of the central nervous system. In the same way that curare prevents the acetylcholine-receptor substance union at the neuromuscular junction, so too does it in the autonomic nervous system.

Although this is said to be only a secondary effect of curare, exerted perhaps only in the presence of large doses, yet it may well be of importance clinically.

In the first place, curare appears to depress markedly the laryngeal and bronchial reflexes, preventing that troublesome complication and bane of the anaesthetist, spasm. Secondly, the effect on the gut has been of some interest. Solis-Cohen (1928) states categorically that curare causes contraction of the gut, and Griffith (1945), the pioneer, has stated that in cyclopropane-curare anaesthesia the gut is indeed contracted, but Cullen (Gross and Cullen, 1945) has produced experimental evidence in animals that it is flaccid and inactive. We have noted marked contraction and activity in most cases, but in others, including most of those anaesthetized with barbiturate-curare only, this irritability has been absent. It is difficult to come to any conclusion in this matter, as the gut reaction will vary with the premedication and the anaesthetic agents. All the anaesthetic and narcotic drugs, not to mention atropine, act on the autonomic ganglia, and it may well be that we are observing a summation of these effects in conjunction with curare.

A clinical difficulty arises in cases of ulcer perforation when we believe that this very real activity of the gut may be responsible for flooding the peritoneal cavity with stomach contents. Furthermore, in a case undergoing transplantation of the right ureter under cyclopropane curare anaesthesia, the ureter had to be inserted into the ascending colon, as the descending part was so contracted that it was impossible to mobilize it. This excessive contraction is never seen when the barbiturates are used to produce anaesthesia.

Present pharmacological opinion is that the liver and kidneys are completely unaffected by curare, but its action on the heart and cardiovascular system is a matter of some importance. The information available up to now has been of doubtful value, for one has never been quite certain which particular extract or preparation was being used. Certain extracts of curare, curine in particular, are known to be potent cardiac poisons. As it seemed that tubocurarine was a definite and specific substance it was clearly of value to investigate its cardiac effects further. Moreover, our clinical results led us to believe that the drug might have some effect on the myocardium.

This work is still in progress, but one of us (T. C. G.) has observed the effect of tubocurarine on the electrocardiogram in a number of cases in the human subject, and with the assistance of Dr. Gregory, of the Department of Physiology in the University of Liverpool, has estimated the result when this material is injected into the Starling heart-lung preparation in dogs. The investigation has progressed sufficiently for us to say that d-tubocurarine produces no effect on the electrocardiogram in the doses in which it is used clinically (fig. 1), and on injection into the heart-lung preparation in dogs, using a dosage vastly greater than anything ever likely to be used in humans, no effect whatever has been observed on the cardiac rate output, or on the venous pressure. As the output is maintained and the venous pressure unaltered, it can justifiably be assumed that there is no alteration in the coronary flow.

FIG. 1.—Electrocardiogram taken seven minutes after the administration of 0.5 grammes pentothal and 20 mg. curare.

It must be emphasized that, in spite of this, curare must be used only with the greatest possible care to maintain full and very complete oxygenation, otherwise the patient's condition will rapidly deteriorate. Especially is this so in those cases having a poor myocardium, for they cannot cope with any sub-oxygenation after curare.

We had employed curare in only a few cases when it became obvious that some form of synergism existed between the drug and the barbiturates, and a further synergism between this combination and any inhalational agent which might be used, such as ether or cyclopropane.

Four facts led us to this conclusion:

(1) From experience we know the dose of barbiturate required to prevent "movement response" to painful stimuli (incision of the skin) in the average patient. For convenience let us call this the minimal anæsthetic dose (M.A.D.).

(2) Curare is not an anæsthetic, and in small doses does not prevent movement. 17.5 mg. were given to a conscious patient. He was still able to react by movement to a noxious stimulus.

(3) The administration of the combination of 15 mg. of curare and a dose of barbiturate less than the M.A.D. produces a completely anæsthetic and motionless patient.

(4) If any inhalational anæsthetic is used to supplement this barbiturate-curare combination, only a minimal amount is required to produce deep anæsthesia.

Signs of anæsthesia and curarinization.—One of our first observations was that here one is deprived of all the ordinary classical signs for estimating the depth of anæsthesia. The eye reflexes, corneal and conjunctival, owing to paralysis, are absent or sluggish, and the ordinary respiratory signs are modified, for at any rate in upper abdominal operations sufficient curare must be given to paralyse the intercostals. The three criteria which do remain are the pulse, respiratory rate, and the anæsthetist's experience.

Frequent observation of the pulse is essential; the first sign of inadequate anæsthesia is a rising pulse-rate and failure to notice this may result in the onset of severe shock due to inadequate narcosis. An increase in respiratory rate will also give warning, provided the patient is not apnœic.

The anæsthetist's experience is often the best guide as to the amount of any particular anæsthetic required to keep a patient in a light plane, and the necessity for the would-be user of curare to have this experience cannot be over-emphasized. At the same time, the danger of a paralysed patient waking up and becoming all too conscious of what Sassoon describes as "the dull opiate throb which was his wound" is non-existent, for in the dosage in which it is used, as already stated, curare does not prevent the small movements of a limb which indicate returning consciousness. An observation was made by Ranyard West (1936) that some specimens of curare had a "lissive" action, producing relaxation without actual paralysis. With tubocurarine a perfectly relaxed abdominal musculature may be present in a patient who is still able to respond to painful stimuli by movements of a limb.

There are two signs of curarinization which must be mentioned. The first is the typical respiration characterized by a pushing-out of the lower part of the chest and of the abdomen with each diaphragmatic contraction, and accompanied by a jaw and tracheal tug. This is not the same as the gasping respiration seen in deep ether anæsthesia, when a partially paralysed respiratory centre is endeavouring to cope with the situation. It is at this point that all effort should be concentrated on ensuring full ventilation of the lungs. Should this not be maintained, the condition will deteriorate, and the surgeon will be embarrassed by the exaggerated diaphragmatic excursion. In this event control of the respiration with the rebreathing bag is easily attained.

The second sign, and a most valuable one, is the ease with which the lungs may be inflated by pressure on the rebreathing bag (Morton, 1945). The absolute intercostal and abdominal relaxation, with the complete absence of laryngeal spasm, makes this manœuvre easy and satisfying.

Recovery.—Any therapeutic innovation must be judged first on the dangers involved in its exhibition to the patient, and secondly on the results obtained.

In respect of the dangers involved in the use of this drug they are real, but so are they throughout the whole realm of anæsthesia. It can be stated that in the hands of the competent anæsthetist, fully conversant with the treatment of the apnœic patient, and with the dosage and technique already described, far from being a danger it will prove an incomparable boon.

Regarding the second criterion, the results of the administration of tubocurarine may be regarded from the point of view first of the surgeon and secondly of the patient.

patient is able to tolerate straight away, without distress, an anæsthetic vapour strong enough to maintain the anæsthesia should this be desired. Induction time is thus tremendously shortened.

With this dose bronchoscopy is easily performed, and because of the relaxation of the pharyngeal and anal sphincters, œsophagoscopy or sigmoidoscopy can be carried out with ease.

Patients recover quickly after this form of administration.

(2) For longer procedures in conjunction with the intermittent injection of an intravenous barbiturate. A remote control tap has been devised which facilitates this technique. Its use overcomes two difficulties of administration, namely, the arm can be placed in any position during the operation without fear of the intravenous needle becoming displaced, and precipitation of the barbiturate by the curare is prevented. This is of little importance where pentothal is concerned, since the precipitation is reversible, but it is of major importance if kemithal or other barbiturate is used. The essential details of this apparatus were shown later to the Meeting in a film.

After an induction as described above, small increments of barbiturate and curare are made. 0.1 gramme of pentothal and 2 to 4 mg. of curare are given from time to time as the reaction of the patient to stimuli and the demands of the surgeon dictate. If the length of the operation is such that a dose of more than 1.5 grammes of pentothal or 3 to 4 grammes of kemithal has to be exceeded, which occurs very rarely, we prefer to continue the anæsthesia with minimal amounts of cyclopropane or ether.

(3) As an adjuvant to inhalational anæsthesia. The intermittent fractional injection of a total dose of 15 to 30 mg. of curare is utilized to produce relaxation while still keeping the patient in a light plane of anæsthesia.

Whichever of these three methods is used, oxygen must be supplied in abundance, and preferably by means of a closed circuit, for by this means adequate and complete ventilation of the lungs can be ensured. The importance of this artificial ventilation of the lungs in cases of overdosage must have been known to the Indians of old, for our respected friend Waterton (1812) mentions that: "It is supposed by some that wind introduced into the lungs by a small pair of bellows would revive the poisoned patient, provided that the operation be continued for a sufficient length of time." In order to confirm this, this enterprising traveller performed the following experiment:

"A she-ass received the Wourali poison in the shoulder, and died apparently in ten minutes. An incision was then made in its windpipe, and through it the lungs were regularly inflated for two hours with a pair of bellows. Suspended animation returned. The ass held up her head and looked around, but the inflating being discontinued she sank once more in apparent death. The artificial breathing was immediately recommenced, and continued for two hours more. This saved the ass from final dissolution; she rose up and walked about; she seemed neither in agitation nor in pain."

Was this, written about the year 1812, the first description of controlled respiration, a technique the knowledge and practice of which is common and essential in modern anæsthesia?

Dosage.—The margin between effective and over-dosage is small. In our opinion no exact dosage for weight scale can be worked out, but the very obese require a little more than average and the extremes of age considerably less. Further, it must be remembered that in computing dosage 1 mg. of d-tubocurarine chloride is approximately equivalent to 6.6 units or milligrams of intocostarin. 20 mg. is sufficient to relax the average healthy adult's abdomen; and 25 mg. to paralyse the diaphragm. The effect of this initial dose will last for a varying time up to forty minutes. There is some temporary cumulative effect, so that subsequent doses must be considerably less, and it has been found satisfactory to use 2 to 4 mg. increments for maintenance. We have never had to use a total dosage of more than 45 mg. of tubocurarine, even when prolonged diaphragmatic paralysis was desirable.

Both extremes of age are very susceptible to curare, and small doses only must be used. In the aged—and the drug has been used in patients over 80—an initial dose of 10 mg. is suitable. Children up to 12 years should not be given more than 6 mg. for induction.

It has been stated that when ether is being used the dose of curare should be reduced by one-third, ether itself being said to have a curariform action. This, in our opinion, is a wrong approach to a correct clinical observation.

mitted, but ordinarily would have been tolerated, probably terminated life. It is our opinion that anoxia and not curare was responsible for these fatalities.

The assessment of results following thoracic operations is difficult. Comparative figures are hard to obtain, anæsthetic methods have been constantly changing, and with the advent of curare more extensive surgery has been successfully practised on cases of the poorer risk type, a fact which speaks for itself!

Table III shows the incidence of post-operative pulmonary morbidity in patients undergoing operations in the upper abdomen. These are compared in column 3 against the figures given by three observers, King (1933) and Campbell and Gordon (1942) using various types of anæsthesia for similar operations. It is necessary to point out that it has been considered a post-operative complication if a patient develops a cough with any physical signs, or suffers aggravation of an existing chest disease.

TABLE III.

Operation	No. of cases	Pre-op. chest condition		Post-op. chest condition	Comparative figures
		Minor	Major		
Partial gastrectomy	38	26.3%	—	18.4% }	38.3% }

Total percentages		22.5%	3.2%	12.5%	56.5% (Campbell and Gordon, 1942)
Total number of cases	125	27	4	15	

We have for long subscribed to the view that heavy premedication with opiates is a thing to be deprecated. The result of this, even before the introduction of curare, was the occasional occurrence of restlessness post-operatively, especially when the main anæsthetic agent was one of the barbiturates. The restlessness which has occurred in a small proportion of these cases has, we are sure, been due to following this principle. Coupled with this, the patients are so well that they are able to exhibit a well-marked second stage "coming up," as it were. They are very conscious of any noxious stimuli, such as wound pain, splintage, or inflated catheters.

This unease has only been transient, and does not occur since we adopted the rule of giving as a routine 1/6 grain morphine and 50 mg. pethidine prior to leaving the theatre.

Indications for use.—Every thoracic and abdominal case undergoing a major operation is benefited by the exhibition of curare. The thoracic case benefits from curare in several ways. It is our considered opinion that for this type of surgery the barbiturates are probably the best agents, always provided that the dosage can be kept at a minimum. By their use the inhalation of irritating vapour is avoided, respiration is quiet and, since they are rapidly eliminated, post-operative toxic sequelæ do not appear, and recovery is rapid and uneventful. The addition of curare to this form of anæsthetic technique considerably reduces the amount of the barbiturate required. Cough and spasm are eliminated and control of diaphragmatic movement can be achieved rapidly and at will, yet the full cough reflex is present before the patient leaves the table.

Curare is of very special benefit to the poor-risk patient. The bad chronic chest case who must undergo a major operation even in the upper abdomen is a subject who will owe a lot to the arrow poison.

In peripheral circulatory failure we see a state of affairs that really does call for its use.

In deep anæsthesia the vasomotor central control is disturbed. This has been demonstrated by Zweifach and co-workers (1945) in a series of experiments on animals, in which they observed the power of adjustment of the capillaries of the mesentery to graduated bleedings under various anæsthetics. Under all deep anæsthesia with the possible exception of cyclopropane, the vasomotor compensatory reaction was lost so that the animal did not respond to transfusion as it should. This may not occur under light anæsthesia, and a glance at the pressure curves of patients undergoing abdomino-perineal operations, a procedure likely to cause a degree of shock and involving a change of position, shows striking clinical confirmation of this.

It will be seen that in fig. 4, where the anæsthetic was cyclopropane and ether carried to a deep plane, the blood-pressure falls progressively when the patient is put into the lithotomy position. This phenomenon has been observed constantly and the chart

To the surgeon the results must be satisfactory, for he is presented with "blotting-paper" relaxation at any time and quickly, together with a quiet operating field.

In respect of the patient, many factors must be considered. Dr. Ralph Waters (1944) made a most important observation when he said that the relief of pain has always exacted a price, due in some part to the toxicity of the drugs used, but more often through ineptitude in the care of the patient when under their influence. This price is paid in the operating theatre, and afterwards in the ward. For one pneumonia caused by ether vapour, many more are caused by mechanical obstruction of the airway during the operation or in bed when the patient is lying motionless on his back recovering from the anæsthetic, possibly inhaling vomitus or septic oral secretions.

Again, vomiting with varying degrees of liver and kidney damage may be caused in some part by the anæsthetic agent exhibited, but more often by long periods of anoxia attendant on its use.

How does the method we have described compare with these dicta? First consider the drugs. Curare is completely and very rapidly eliminated. There is no evidence that it has any latent toxicity. The same holds good for the barbiturates in the doses in which they are used. If inhalational anæsthesia is employed to supplement, the amount is so small that the risk of toxic after-effects is non-existent or greatly reduced. During the anæsthesia the patient is ventilated by an atmosphere rich in oxygen and since spasm of the cords is completely eliminated the chance of anoxæmia arising is extremely remote. Vomiting in thoracic cases is now a thing of the past. In abdominal cases, while the incidence appears unchanged, the degree of severity is very much less.

It is on return to the wards that the biggest price is so often exacted. But in these patients the essential reflexes are fully recovered prior to leaving the theatre, and within half an hour they are co-operative, able to do breathing exercises, to cough and expand their chests, and can be left with safety to look after themselves. This has meant a tremendous reduction in post-operative pulmonary morbidity.

Between us we have given curare to 1,049 cases, and Table II shows the extent of the ground we have covered.

Two deaths which might be attributed to the anæsthetic have occurred. They happened early in the series. The post-mortem findings in each case showed gross myocardial damage, and that, coupled with a degree of anoxia which should never have been per-

Professor Charles A. Wells mentioned that much of the work had been done in, and with the co-operation of, the Department of Surgery for which he was newly responsible in Liverpool.

Every advance demanded its own sacrifice, but in this instance there had been no human sacrifice. To the contrary, he was satisfied that many patients were alive and well to-day who would not have survived other anaesthetics and, further, that satisfactory operative relief had been made available, through curare, to many patients to whom it would otherwise have been denied.

The surgeon was given a quiet field with full relaxation without apparent prejudice to the general condition of the patient. If the anaesthesia was becoming light, warning was often given by phonation or the movement of a limb. Abdominal straining was a late feature of the waking process and a deeper plane could be recovered in a few seconds, before any embarrassment was experienced.

On returning to the wards, the patients not only wakened quickly but were unusually co-operative and were able to begin, almost at once, the limb movements and breathing exercises which were so vital to quick recovery and low morbidity.

Dr. F. Prescott described some experiments that he had made in collaboration with Dr. Organe. In the unanaesthetized subject it was found that 10 mg. of d-tubocurarine chloride intravenously had very little effect in relaxing voluntary muscle. Only the muscles of the face and eyes were affected to any extent. A dose of 20 mg., however, produced paresis of the muscles of the face, neck, arms, legs and abdomen in that order. Speech was lost but not the cough reflex. Respiration was not consciously affected, but spirometer readings showed that the tidal air was diminished by about one-third. A dose of 30 mg. intravenously produced complete paresis of all voluntary muscle and almost complete cessation of respiration, necessitating artificial respiration to prevent asphyxia. No analgesic action was observed. A test was made to see if fractional administration gave relaxation without respiratory suppression. A dose of 30 mg. given intravenously at the rate of 1 mg. per minute did not produce adequate relaxation. The subject was not curarized and was able to sit up ten minutes after the injection. A curarizing dose in the conscious patient lasts for twenty to thirty minutes. A more prolonged effect without depression of respiration was produced by giving 15 mg. intravenously and 15 mg. simultaneously by the intramuscular route.

Dr. F. Barnett Mallinson said he was surprised at the condemnation of intocostin. He had been using this preparation of curare since the end of 1944 and he had been very satisfied with the results. Using intocostin only he found himself very much in agreement with the speakers' experience of curare, and would add that he had never had to use prostigmin.

He had never used the Burroughs Wellcome preparation, first, because intocostin has worked so well; second, because shortly after he published his preliminary report on curare in anaesthesia (*Lancet*, July 21, 1945) he had had two reprints and a personal communication from Dr. Ranyard West (*Journ. Physiol.*, 1938, p. 437; *Lancet*, February 19, 1938, p. 432) whose work had already been quoted by Dr. Gray, warning him of the dangers of bronchospasm. This he had never encountered with intocostin. He would like to ask the speakers whether they had encountered this complication. Also did they consider that the Burroughs Wellcome preparation would become available in solution, like intocostin?

Liberal oxygen should always be a feature of the accompanying anaesthesia, and he suggested that cyclopropane was thus the best. On the other hand, 2.29 grammes pentothal (a pretty big dose) with N_2O-O_2 for a normal length gastrectomy seemed likely to have been sufficient in itself and hardly to have needed the addition of curare.

A true evaluation of the real safety of curare must await cases in their tens of thousands. Chloroform was widely considered to be the most dangerous of all anaesthetics; but taking into account its accepted mortality rate, it might require some 4,000 administrations before the anaesthetist had a death. He doubted if the total published administrations of curare yet reached 4,000.

Dr. T. A. B. Harris noted, in the series of cases described, that d-tubocurarine had been used in 126 genito-urinary cases. Since, as far as is known, curarine is excreted from the body solely by the kidneys, would Drs. Gray and Halton consider renal inefficiency to be a contra-indication to the use of curarine?

Dr. C. Langton Hewer queried the method of sterilizing curarine chloride. He doubted whether autoclaving the ampoule did in fact sterilize the contained powder.

Dr. Hewer also described several cases of ocular paresis which had occurred after curare had been used. In a series of 37 administrations (mostly for gastrectomy) 19% of patients complained afterwards of difficulty in fully opening their eyes or of blurred vision. In every case symptoms had disappeared by the fourth day. Dr. Hewer pointed out that in myasthenia gravis, a condition very similar to curarization, the patients often complained first of the same symptoms.

Dr. G. S. W. Organe stressed the importance of adequate ventilation as well as adequate oxygenation. In one experiment on a conscious subject the tidal volume was reduced to less than 100 c.c. Although, breathing pure oxygen, there was no cyanosis, there was considerable distress and a feeling of suffocation due, probably, to accumulation of carbon dioxide. The dose was extremely critical. After 10 mg. tubocurarine intravenously on the same subject, the minute volume was 12 litres; after 20 mg. it fell to $7\frac{1}{2}$ litres and after 30 mg.

shown is typical of twenty such. Fig. 5 is illustrative of six similar cases anaesthetized in a light plane with the help of curare. No fall in blood-pressure occurs on the change of position. We attribute this to an intact vasomotor central mechanism, which enables the patient to adapt his circulation to the altered circumstances.

FIG. 4.—Blood-pressure, pulse and respiration in a male patient aged 41, undergoing abdomino-perineal excision of the rectum. Anaesthesia: Hexobarbitone induction, cyclopropane and ether maintenance. (Note the blood-pressure falls when the patient assumes the lithotomy position as indicated by the arrow.)

Contra-indications.—Curare should never be used by anyone who is not fully conversant with the care of the apnoeic patient. Anoxia appears easily and is more serious, especially when there is cardiac inefficiency. Despite laboratory evidence that the drug has no cardiac action, clinically there is no doubt that with this form of anaesthesia patients do not tolerate even a slight degree of anoxaemia.

In abdominal operations when used with cyclopropane it may cause excessive contraction of the gut, and so render surgery more difficult.

Curare should not be used in cases of intestinal obstruction with distension, unless particular care is taken to avoid the uncontrolled regurgitation of the intestinal contents in these patients whose every natural protection has been removed. This also applies to cases with a lung abscess.

The dosage may have to be modified in the presence of renal damage of any consequence.

West has described the occurrence of excessive bronchial secretion and spasm in some of the cases he treated for tetanus. In our series of cases, including many oral endoscopies, this has never been observed.

Finally, this drug should not be used in cases suffering from myasthenia gravis.

CONCLUSION

The road lies open before us, and with a grave and insistent warning to the inexperienced that we are dealing with one of the most potent poisons known, we venture to say that we have passed yet another milestone, and the distance to our goal is considerably shortened.

We express our deep gratitude to Professor Charles Wells, Mr. H. Morriston-Davies, Dr. Minnitt, Mr. J. A. Martinez, and our friends and colleagues, the surgeons, who have made this work possible.

[February 6, 1946]

DISCUSSION ON CARCINOMA OF LOWER ŒSOPHAGUS AND CARDIA

Mr. Norman C. Tanner: Carcinoma of the œsophagus, usually a squamous-celled tumour, and carcinoma of the cardia, usually an adenocarcinoma originating in gastric mucosa, differ in their histology, direction and rate of spread, prognosis and treatment, but the technical problems associated with their extirpation are similar.

The surgical inaccessibility of the œsophagus was one of the chief technical barriers to its extirpation and many ingenious approaches to it have been described and used. The poor suturing qualities of the œsophagus and the apparent impossibility of restoring intrathoracic continuity gave rise to every conceivable variety of antethoracic œsophagoplasty being tried. Now, as a result of improvements in thoracic surgery, in anaesthesia and in chemotherapy, a more merciful and more direct approach to these cases has arisen, making resection and immediate restoration of continuity a possibility in nearly all the early œsophageal and upper gastric neoplasms.

The abdominal approach.—A purely abdominal resection, or total gastrectomy, is a suitable operation where the upper limits of a gastric tumour just encroach on the lower limits of the cardia. We are considering, however, the tumour which starts in the region of the cardia and has œsophageal as well as gastric extension. While a palliative excision of the hopeless case may be justifiable by a purely abdominal approach, if curative surgery is aimed at, the abdominal approach will be found insufficient in such cases, for the tumour mass gets in the way of œsophageal anastomosis. The œsophagus seems to be shortened and made rigid by growth and one will generally find, if the cardia is really involved, that the transection is through or lamentably near the edge of the growth.

Collo-abdominal resection	3				
Thoracic or abdomino-thoracic resection	5				

I have never performed œsophagectomy without some attempt at immediate reconstruction of the œsophagus. Earlier on I erroneously formed the opinion that where possible thoracotomy should be avoided and antethoracic anastomosis favoured in the poor risk case. Therefore I will first describe my experiences with extrathoracic anastomosis.

Extrathoracic anastomosis.—Three resectable adenocarcinomas of the cardia were treated on similar lines. In each case a mid-epigastric incision was made, and the part of the stomach involved mobilized. Next the œsophageal hiatus was enlarged by an anterior incision in the diaphragm, exposing the base of the pericardium. Into the opening the whole hand could be placed behind the heart, and the lower œsophagus freed under vision. The middle œsophagus was freed blindly and another incision in the left suprasternal notch enabled the upper œsophagus to be mobilized, the hand in the posterior mediastinum doing most of the work. Under vision the œsophagus was divided well above the growth and the cardia and affected part of the stomach and glands removed, the rest of the œsophagus being pulled out of the neck. It was then pulled under the skin of the chest wall.

The first case so treated was a man aged 73. The pyloric antrum only was preserved, as the growth involved half the stomach, and the pyloric antrum was pulled under the skin of the chest wall and anastomosed to the cut end of the œsophagus. The intention was to enable the patient to feed for a few days and when the œsophagus sloughed to do a dermatoplasty after the method of Rovsing. Post-operatively a left tension pneumothorax was treated by needling and pulmonary œdema on the second day was treated by postural drainage. After that he ate and drank and seemed well. On the eleventh day the œsophagus was exposed and the sloughing part removed. A rubber tube was stitched into the pyloric antrum. Unfortunately the latter was an awkward shape and leaked badly, so that it was difficult to feed him. Eventually he went downhill and died at the end of a month.

to only 2 litres. In curare we had not found the answer to all post-operative complications—in one man with perforated gastric ulcer there developed a post-operative lobar collapse. The general condition of patients after major upper abdominal operations was as good as when muscular relaxation had been obtained with intercostal nerve block and the procedure involved was much simpler and quicker. Tracheal intubation was not called for in such cases as it was particularly easy to maintain a clear airway. He had not seen bronchospasm and had used curarine chloride to relieve laryngospasm.

Dr. A. H. Galley, in answer to a query raised by Dr. Geoffrey Organe over an experiment he had performed on a conscious colleague by injecting tubocurarine chloride, said that the respiratory distress suffered by the subject of Dr. Organe's experiment was due to an accumulation of carbon dioxide in the blood-stream in excess of the normal. If one was subjected to simple and uncomplicated oxygen lack, unconsciousness would ensue without any feeling of distress; but, if one held one's breath, or the air passages were blocked, or ventilation became so shallow as to interfere with respiratory exchange, then carbon dioxide—having little or no means of escape—would accumulate with subsequent distress. Although this feeling would not be experienced by the unconscious patient, Dr. Organe's experiment did remind them that such shallow breathing would inevitably lead to carbon dioxide accumulation with the well-recognized cycle of events which led to circulatory collapse. It might be better, therefore, always to employ closed circuit machines when administering oxygen to curarized patients.

Dr. H. W. Loftus Dale had also observed that operations such as cholecystectomy, gastrectomy, and abdomino-perineal excision of rectum could be performed under light cyclopropane anaesthesia and curare with no, or insignificant, alterations in pulse and blood-pressure.

Since curare produces no sensory loss, and only light planes of general anaesthesia were employed, there seemed nothing to prevent "nociceptive" afferent stimuli from reaching the vasomotor centre. Unless this could be explained by synergism between curare and the general anaesthetic agent, as suggested by the openers, doubts must be cast on the theories of Crile and others concerning "reflex shock". A practical point: In one case in which an endotracheal tube packed off with gauze was used to protect the tracheo-bronchial tree against aspiration, a seal tested and found gas-tight became totally inadequate after the injection of curare owing to relaxation of the pharyngeal muscles, and a considerable amount of extra packing was required to ensure against leakage.

Dr. J. W. Trevan said that there was little doubt that the active principle of intocostrin was d-tubocurarine. This was claimed by the makers, and the speaker had examined the alkaloid separated by Dr. Copp from a sample of intocostrin, which accounted for the activity of the extract and which as far as tests could be carried out on the small sample proved to be d-tubocurarine. He found that 1 unit of a sample of intocostrin he had examined was equal in activity to 0.17 mg. of d-tubocurarine. He said that confusion had arisen by labelling doses in terms of milligrammes of a preparation of curare. d-Tubocurarine apparently differed from crystalline curarine from *strychnos* species in having a strong curarizing activity without other marked toxic properties. d-Tubocurarine was derived from *chondrodendron tomentosum*. Prostigmine and physostigmine were true antagonists to d-tubocurarine, in a dose about 1/20 to 1/10 of the dose of d-tubocurarine. Very large overdoses (3 to 4 times paralyzing dose) were not, however, antagonized by prostigmine or physostigmine. He saw the experiment on Dr. Prescott and could not agree that the prostigmine injected did not accelerate his recovery. The antagonism of tubocurarine by prostigmine on isolated voluntary muscle was quite certain.

The Openers, in reply, expressed their interest in Dr. Prescott's observations; clinically they were of great value. Answering Dr. Mallinson they reiterated their remarks on the inconsistent action of intocostrin. d-Tubocurarine chloride, on the other hand, was a specific alkaloid and produced a constant and predictable action in the human subject and on experimental animals. The gastrectomy which required 2.29 grammes of pentothal lasted two hours yet the patient was able to answer questions before leaving the theatre; his recovery was uneventful. Was Dr. Mallinson able to produce that result with pentothal alone?

Comparison between chloroform and tubocurarine was not logical, for while the former was a proved somatic poison, all clinical and laboratory evidence showed that this was not so with the latter drug. In reply to Dr. Harris, gross renal damage, proved or suspected, was a contra-indication to full doses of tubocurarine.

In reply to Dr. Langton Hewer, no case of ocular paresis had been seen in the series under discussion. With regard to sterilization, it was admitted that the method at present in use was open to criticism and it was under review. Nevertheless, samples of the solutions taken at random had always proved sterile.

All the points made by Dr. Organe were of great importance. They could not be stressed enough especially to those anaesthetists who were about to use tubocurarine for the first time.

Dr. Trevan's observations were noted with interest and further clinical investigations would obviously have to be made.

[February 6, 1946]

DISCUSSION ON CARCINOMA OF LOWER ŒSOPHAGUS AND CARDIA

Mr. Norman C. Tanner: Carcinoma of the œsophagus, usually a squamous-celled tumour, and carcinoma of the cardia, usually an adenocarcinoma originating in gastric mucosa, differ in their histology, direction and rate of spread, prognosis and treatment, but the technical problems associated with their extirpation are similar.

The surgical inaccessibility of the œsophagus was one of the chief technical barriers to its extirpation and many ingenious approaches to it have been described and used. The poor suturing qualities of the œsophagus and the apparent impossibility of restoring intrathoracic continuity gave rise to every conceivable variety of antethoracic œsophagoplasty being tried. Now, as a result of improvements in thoracic surgery, in anæsthesia and in chemotherapy, a more merciful and more direct approach to these cases has arisen, making resection and immediate restoration of continuity a possibility in nearly all the early œsophageal and upper gastric neoplasms.

The abdominal approach.—A purely abdominal resection, or total gastrectomy, is a suitable operation where the upper limits of a gastric tumour just encroach on the lower limits of the cardia. We are considering, however, the tumour which starts in the region of the cardia and has œsophageal as well as gastric extension. While a palliative excision of the hopeless case may be justifiable by a purely abdominal approach, if curative surgery is aimed at, the abdominal approach will be found insufficient in such cases, for the tumour mass gets in the way of œsophageal anastomosis. The œsophagus seems to be shortened and made rigid by growth and one will generally find, if the cardia is really involved, that the transection is through or lamentably near the edge of the growth.

1940-1945 ADENOCARCINOMAS INVOLVING CARDIA—38	
No operation	2
Laparotomy, inoperable, nil done	4

" " Palliative total gastrectomy	13
Collo-œsophageal resection	3
Thoracic or abdomino-thoracic resection	5

1940-1945 SQUAMOUS-CELL CARCINOMA OF LOWER ŒSOPHAGUS—14	
No operation	2
Gastrostomy only	5
Thoracotomy, inoperable, nil done	1
Thoracic resection and antethoracic œsophagoplasty	4
Intrathoracic resection and anastomosis (plus 1 simple ulcer)	2

I have never performed œsophagectomy without some attempt at immediate reconstruction of the œsophagus. Earlier on I erroneously formed the opinion that where possible thoracotomy should be avoided and antethoracic anastomosis favoured in the poor risk case. Therefore I will first describe my experiences with extrathoracic anastomosis.

Extrathoracic anastomosis.—Three resectable adenocarcinomas of the cardia were treated on similar lines. In each case a mid-epigastric incision was made, and the part of the stomach involved mobilized. Next the œsophageal hiatus was enlarged by an anterior incision in the diaphragm, exposing the base of the pericardium. Into the opening the whole hand could be placed behind the heart, and the lower œsophagus freed under vision. The middle œsophagus was freed blindly and another incision in the left suprasternal notch enabled the upper œsophagus to be mobilized, the hand in the posterior mediastinum doing most of the work. Under vision the œsophagus was divided well above the growth and the cardia and affected part of the stomach and glands removed, the rest of the œsophagus being pulled out of the neck. It was then pulled under the skin of the chest wall.

The first case so treated was a man aged 73. The pyloric antrum only was preserved, as the growth involved half the stomach, and the pyloric antrum was pulled under the skin of the chest wall and anastomosed to the cut end of the œsophagus. The intention was to enable the patient to feed for a few days and when the œsophagus sloughed to do a dermatoplasty after the method of Rovsing. Post-operatively a left tension pneumothorax was treated by needling and pulmonary œdema on the second day was treated by postural drainage. After that he ate and drank and seemed well. On the eleventh day the œsophagus was exposed and the sloughing part removed. A rubber tube was stitched into the pyloric antrum. Unfortunately the latter was an awkward shape and leaked badly, so that it was difficult to feed him. Eventually he went downhill and died at the end of a month.

The second was a man aged 71, with a carcinoma of the cardia and 2 cm. of the œsophagus. Less stomach had to be resected here and so a tube of greater curve of the stomach, after the method of Rutkowski, was made. This time much less œsophagus was retained, and sutured to the tube of greater curvature. The patient stood the operation well, but the anastomosis began to leak in five days and was resutured. He died on the fifteenth day from cellulitis of the chest wall.

The third case was a very atheromatous man of 66. The stomach was severely involved in the growth as well as œsophagus, and a total gastrectomy and splenectomy had to be done. This time the jejunum was widely mobilized after the method of Roux and Yudin and the œsophagus anastomosed to jejunum. Again it was obvious that the œsophagus would slough, for in view of the atheroma it was only possible to bring the jejunum up to mid-sternal level. Therefore the lower œsophagus and anastomosis were left above the skin level with the intention of enclosing it in skin shortly after. The patient withstood the operation well and was taking diet well on the day after operation. On the second post-operative day, the skin of the chest wall was mobilized to form a skin tube round the exposed œsophagus. He died on the fourth post-operative day of pulmonary œdema.

Four cases of antethoracic œsophagoplasty performed after resection of squamous-celled tumours of the lower œsophagus were briefly: exposure of the growth by right or left thoracotomy, removal, and then pulling the upper œsophageal stump out of an incision in the left suprasternal notch. After closing the chest the abdomen was opened and the stomach completely mobilized, and drawn out of the abdomen and then brought under the skin of the chest wall to meet the œsophagus. This type of anastomosis has been successful in a case of Hermon Taylor's and was originally suggested by Kirschner for innocent stricture of the œsophagus.

In the first case, a man of 63, I made the mistake of not resecting the tumour before pulling the upper œsophageal stump out of the neck, and so he developed a post-operative mediastinal emphysema and died within twenty-four hours. In this case an attempt to make the œsophageal ends meet failed and so the cardia was left as a gastrostomy opening.

In the second case, a man of 68, the cardia was removed with the growth and a satisfactory anastomosis was made between the œsophagus and fundus of stomach. This patient died on the third post-operative day, autopsy showing severe pulmonary œdema and purulent bronchitis.

The third case, a man aged 50, had a very extensive growth, both pleural cavities being opened, and he died of pulmonary œdema on the second day.

The fourth case, a fragile and wasted woman of 64, had a similar procedure and did well at first. However, the suture line leaked on the eleventh day and was resutured. This recurred on the nineteenth day. At the end of a month a local dermatoplasty was done. She eventually died at the end of nine weeks of exhaustion from repeated leaks.

These cases demonstrated that while they are radical and the aged patient in most cases easily withstood the surgical shock, he could not withstand the exhaustion following repeated leaks from the subcutaneous anastomosis.

Intrathoracic anastomosis.—The eight cases of intrathoracic reconstruction were as follows:

Adenocarcinoma of the cardia:

The first was admitted in December 1943. A laparotomy was done, and carcinoma involving the upper quarter of the stomach and coronary glands was found with a small metastasis in the liver. In view of his comparative youth (48) the operation was continued: the stomach being freed and divided below the growth. Next the left chest was opened, the diaphragm opened and after resection of the lower third of the œsophagus and upper quarter of stomach, an œsophago-gastric anastomosis was made. He made a good recovery interrupted by a mild pleural infection. He went back to work for several months but died of metastases eleven months later.

The next, a man of 65, with congenital choreo-athetosis, was found to have a neoplasm fairly localized to the cardia and lower œsophagus. His growth was exposed by removal of the 8th left rib and parts of the 5th, 6th and 7th, and after division of the diaphragm the growth was mobilized. The lower half of the œsophagus, cardiac end of stomach and spleen were removed, and œsophagus united to gastric stump. He made an excellent recovery and still swallows well nine months after the operation. However, the growth was extensive, with metastases in three lymph glands, and he has now developed a small umbilical metastasis.

The third case was a man aged 72, with a similar tumour. A similar left major thoracotomy exposed the growth. Unfortunately, the tumour was found to be infiltrating the œsophageal hiatus in the diaphragm and so an extensive operation was necessary, with removal of the upper quarter of stomach and glands, lower third of œsophagus, spleen and ring of diaphragm. Post-operative purulent bronchitis and pulmonary œdema were treated by postural drainage. He improved, but suddenly died on the eleventh day, from pulmonary embolus.

The fourth case, an obese man of 65, had a similar tumour of the cardia, but there was also a large hiatal hernia, and it appeared that the growth had originated in, or had caused, a short œsophagus. A similar operation was performed but he developed pneumonia and died on the fifth day.

The fifth case was interesting in that there was very extensive gastric and œsophageal growth in a patient aged 68 necessitating total gastrectomy and splenectomy. The upper jejunum was divided and mobilized after the method of Roux and Yudin, and the proximal

end implanted lower down in the jejunum. The jejunum was passed through the transverse mesocolon and the abdomen closed. The left chest was then opened and the œsophagus further mobilized, and then the stomach, spleen and lower œsophagus were pulled out of the chest and removed. An anastomosis was made between the œsophageal stump and the jejunal end, and the chest closed with drainage (fig. 1). He made an excellent recovery and before discharge was able to take a three course meal with a glass of stout, was keen on his meals and found brandy gave him a pleasant epigastric glow!

FIG. 1.—X-ray of barium swallow following intra-thoracic anastomosis of cut end of œsophagus to end of mobilized jejunum.

Squamous-celled œsophageal carcinomas:

The first was an atheromatous and somewhat bronchitic man of 75, who had a squamous-celled carcinoma at the junction of the middle and lower œsophagus proved by œsophagoscopy. The tumour was approached by a left-sided thoracotomy. He had an advanced tumour adherent to the lung margin and with enlarged glands. A most fortunate circumstance was that he had such an extreme degree of tortuosity of the aorta resulting from atheroma that the growth had lost any relationship to the aorta, making removal easier. The growth was removed, together with glands, adjacent pleura and a small fragment of lung tissue. The stomach was mobilized, brought through the diaphragm and anastomosed to the œsophageal stump. This patient made an excellent recovery, interrupted by a short period of cardiac insufficiency, but was up, about and eating well at the time of his discharge. I believe this patient is the oldest to have survived this type of operation (75)—a fact which is of importance in a disease which is especially one of old age.

The next patient, a female aged 67, with paralysis agitans, was diagnosed radiologically as carcinoma of the lower œsophagus: operation was on the same lines as the last patient and she made an excellent recovery and was discharged well. Section, however, showed the stenosis to be due to scarring of a peptic ulcer, but I have included it as it presents a similar technical problem.

The last carcinoma of the lower œsophagus in this series was just above the junction of the middle and lower thirds, and I already felt with these in this position that there was some difficulty in making a section really well above the tumour, if the anastomosis was to be made under the aortic arch. One could, of course, transfer the upper stump above the arch, and make a high anastomosis lateral to the aorta, but then one finds that, at the beginning of the operation, one is working in difficulty in the lower part of the wound, and the rest of the operation one is working in difficulty in the highest part of the wound. Now in June 1945 I had a patient with a high carcinoma of the œsophagus in whom I first opened the abdomen and freed the stomach along both curvatures, leaving the right gastric and right gastro-epiploic arches intact. Next I widely opened the diaphragm by cutting forwards from the œsophageal hiatus to expose the base of the pericardium and then largely under vision mobilized the lower quarter of the œsophagus.

Next I opened the right chest high up by excising the 5th rib. The growth was inoperable but it was a simple matter by traction on the œsophagus to pull the stomach into the right chest and make a short circuit between fundus and higher œsophagus.

I decided to use a similar method on this patient, a rather alcoholic man aged 69, whose growth was at 35 cm. from the incisors. The stomach and lowest œsophagus were freed abdominally, and the diaphragm opened. Next I performed a right thoracotomy removing the 6th rib and the azygos vein was tied and divided. The growth was very widely removed, and the stomach easily pulled up and its fundus anastomosed to the œsophageal stump (fig. 2). X-ray shows a high anastomosis. This patient made an excellent recovery interrupted by a transfusion jaundice, but was discharged eating and feeling well.

FIG. 2.—X-ray of barium swallow showing very high intrathoracic anastomosis and stomach shadow above level of clavicles.

Mr. Ivor Lewis described a similar but two-staged method in a recent Hunterian Lecture and had a success by it before my first case. However, to one who does not claim to be primarily a thoracic surgeon I think mobilization of the lower œsophagus and division of the diaphragm through the abdomen is easier than the ingenious trans-thoracic method favoured by Mr. Lewis, and it seems that the patients will tolerate a one-stage procedure.

Resection of the Cardia and Lower Œsophagus

(1) *Antethoracic anastomoses*.—7 cases, average age 65: 3 survived two to nine weeks. None left hospital.

(2) *Intrathoracic anastomoses*.—8 cases, average age 66: 6 left hospital well.

(3) *Abdominal resections*.—Mostly palliative—13.

As regards feeding these patients pre-operatively none had a gastrostomy or jejunostomy, but all were given as much fluid protein by mouth as they could take, and in addition had intravenous plasma and saline daily.

The anaesthesia in each case was a posterior intercostal block on the side of the thoracotomy, and abdominal field block on the other side if the abdomen was to be opened, and each was given cyclopropane through an intratracheal tube with an inflatable cuff, by Dr. P. Peterson.

No patient had either a temporary or permanent interruption of the phrenic nerve.

Post-operatively the most troublesome complication was pulmonary œdema, which usually arose about the second day and was often accompanied by cardiac irregularity and bronchitis. The treatment we found most satisfactory was postural drainage and postural coughing, the bed being placed in the Trendelenburg position several times a day.

CONCLUSIONS

It is obvious from my results that I must favour intrathoracic anastomoses.

Finally, I would like to point out several advantages which one may gain from a preliminary laparotomy, except in the very localized and very low œsophageal tumour.

(1) Greater ease in freeing the stomach and a better dissection of the subdiaphragmatic and coronary lymph glands, and of the lesser omentum.

(2) Greater facility in mobilizing the jejunum in the rare cases where a loop of jejunum is too short to reach the œsophagus.

(3) Greater ease in closing the duodenum in cases where the whole stomach has to be removed.

(4) The ability, after dividing the diaphragm from below, to insert the hand in the posterior mediastinum and to palpate the growth, and possibly avoid a fruitless thoracotomy. In one case by this means I was able to ascertain with certainty that an œsophageal neoplasm was invading the bifurcation of the trachea.

(5) The ability to make a higher resection and anastomosis very comfortably by combining abdominal mobilization of the stomach and lower œsophagus with a high right thoracotomy.

Mr. P. R. Allison: Carcinoma involving the cardia may be of gastric or œsophageal origin, and it is often impossible to distinguish these on clinical and radiological evidence only. From the point of view of surgical treatment they are one problem, though differences in extent of involvement of stomach or œsophagus may need corresponding modifications of procedure. All these growths are hopeless when attacked from the abdomen, but the approach through the left pleural sac, with splitting of the diaphragm, has offered a good hope of palliation and some chance of radical treatment. The work is still young and includes much which might be called experimental so that the figures quoted must not be accepted as indicating all that can be offered to these patients. Progress is being made in technical details from one patient to the next, and many years must elapse before the results of these can be gauged. As in all forms of cancer the urgent call is for earlier diagnosis, and it is one of the purposes of this paper to indicate some of the ways in which this could be achieved.

Out of 100 patients suffering from malignant obstruction in the region of the cardia, 41 were found to have squamous carcinoma, 53 adenocarcinoma, 4 undetermined, 1 reticulum-cell sarcoma, and 1 Hodgkin's sarcoma. Both œsophageal and gastric growths were more common in males than in females, and the ages varied from 30 years to 77 years (Table I).

TABLE I.

	Males	Females	Oldest	Youngest	No. between 30 and 40 yrs.	Average age
Squamous carcinoma 41	29	12	73	30	3	55
Adenocarcinoma 53	35	18	77	31	6	57

DIAGNOSIS

The commonest symptom of which patients complain is dysphagia, and one of the main causes of delay in treatment is the astonishing pertinacity with which they carry on before seeking advice. In this series the average duration of dysphagia after which the patients were first seen was five months and this was the same for the œsophageal as for the gastric growths. The longest time was two and a half years. The longest time-lapses were found in those whose investigation had been incomplete or faulty and whose symptoms had been partially relieved by the passage of bougies or Hurst's mercury tube. This latter instrument, which has been so useful in its day, should now be ejected from our armamentarium, as its place in the treatment of cardiospasm should be taken by Negus' hydrostatic dilator, and its use in other conditions is both illogical and harmful. Dysphagia may sometimes be intermittent due to the sloughing away of masses of growth or to the alternate impaction and dislodgement of unchewed solid food. There is no relation between the length of history or rate of progress of dysphagia on the one hand, and the extent of growth or degree of malignancy on the other. Emphasis should be laid on this point when the question of suitability of a patient for operation is being considered. In one case where the growth attained huge dimensions, there was no history of dysphagia at all but only feul eructations. It is true in the main, however, that a growth starting in the abdominal œsophagus or in the stomach close to the cardia is more likely to give rise to dysphagia as a first symptom than those further away. A carcinoma in the body of the stomach may cause loss of appetite, loss of vigour and anæmia for some time before it reaches the cardia and produces dysphagia.

Pain is variable in its incidence, type and degree. It is often absent altogether even in hopeless cases. Epigastric discomfort or pain behind the lower end of the sternum

Next I opened the right chest high up by excising the 5th rib. The growth was inoperable but it was a simple matter by traction on the œsophagus to pull the stomach into the right chest and make a short circuit between fundus and higher œsophagus.

I decided to use a similar method on this patient, a rather alcoholic man aged 69, whose growth was at 35 cm. from the incisors. The stomach and lowest œsophagus were freed abdominally, and the diaphragm opened. Next I performed a right thoracotomy removing the 6th rib and the azygos vein was tied and divided. The growth was very widely removed, and the stomach easily pulled up and its fundus anastomosed to the œsophageal stump (fig. 2). X-ray shows a high anastomosis. This patient made an excellent recovery interrupted by a transfusion jaundice, but was discharged eating and feeling well.

FIG. 2.—X-ray of barium swallow showing very high intrathoracic anastomosis and stomach shadow above level of clavicles.

The treatment we found most satisfactory was postural drainage and postural coughing, the bed being placed in the Trendelenburg position several times a day.

simple stricture and "cork-screw œsophagus". The ultimate differentiation should depend on œsophagoscopic appearances and, if necessary, biopsy. There seems to be no record yet of a simple peptic ulcer of the œsophagus undergoing malignant change.

A final diagnosis of the cause of dysphagia should not be made in any but the most decrepit without an endoscopic examination. The œsophagus above a malignant stricture may or may not be dilated, but if dilatation is present it is never extreme. Fluid and food retention may be noted, and the mucous membrane shows a corresponding amount of chronic inflammation. This last is most marked just above the stricture but it is hardly ever the angry change which may be seen in the acid digestion of a case of simple peptic ulcer. The site of obstruction may be smooth and funnel-shaped where the growth has extended mainly in and outside the wall, or masses of neoplasm may be seen in the lumen. A careful note should be made of the smell. Sometimes ulceration is associated with a mixed infection which produces a most offensive odour and in these cases the greatest care must be exercised to avoid contamination of the mediastinum at operation. If the growth starts in the stomach and has not invaded the œsophageal mucosa, a hardness or rigidity or deformity may be noted at the lower end. The instrument, which normally passes easily into the stomach, meets an obstruction and the cardia fails to relax. If a bougie is passed gently into the stomach at this stage the stenosis can be appreciated by the hand. A rigidity and fine roughness is transmitted, and felt to be quite unlike the soft grip sometimes experienced in cardiospasm. It may be possible to confirm the diagnosis by biopsy even when the growth itself cannot be seen.

PATHOLOGY

The primary growth, whether it be in the œsophagus or stomach, may extend mainly into the lumen of the organ. In this case a polypoidal mass occurs which may attain large proportions before giving rise to many symptoms. Such tumours are more likely to be found in the œsophagus than in the stomach, for in the latter position peptic digestion with sloughing of the mass usually occurs. The spread within the wall may take place in the submucous, muscular or surrounding tissues. It is not uncommon in the œsophagus to find islands of growth separated from the main mass by normal mucosa. It is important to determine this when the patient is œsophagoscoped so that impalpable growth is not left behind at operation. In some of the cases examined there has been a notable spread of growth within the muscular tissue of both stomach and œsophagus. In one gastric growth nerves were found containing tubular extensions of malignant cells. When the growth extends beyond the œsophagus it invades the mediastinal tissues, pleura and lung. Perforation into the lung with gangrene and a spreading bronchopneumonia is one of the accidents which may cause death in these patients. At the cardia or in the body of the stomach a direct spread may occur either to the left lobe of the liver or the body of the pancreas. Spread to lymphatic glands may occur early or late depending on the type of tumour. An appreciation of the lymphatic paths is essential if a radical operation is to be employed. Those in the stomach have been worked out by Jamieson and Dobson (1907), and it is on their work that the following description is based.

The lymphatics of the upper half of the stomach pass mainly along the left gastric vessels through or past various gland stations to the glands around the celiac axis. Some vessels, particularly from that area where the blood drainage is through the vasa brevia, pass in the gastrosplenic omentum or over the top of the lesser sac of peritoneum into the pancreatico-lenal glands. The greater curvature area drains along the right gastro-epiploic vessels to the subpyloric glands, but this region is only of importance where the growth is so extensive as to need a total gastrectomy. In addition to these three main catchment areas there is a lymphatic pathway from the cardia through the œsophageal hiatus of the diaphragm upwards to the glands in the posterior mediastinum. Vessels may by-pass their immediate gland stations and drain into other glands some distance away and, in the post-mortem room, a specimen has been seen where a growth at the cardia was associated with a lonely metastasis in a gland on the right side of the œsophagus at the level of the vena azygos major where this vessel enters the superior vena cava.

The lymphatics of the lower œsophagus drain mainly into the para-cardiac and superior gastric glands, communicating freely at the cardia with the gastric lymphatics but some pass upwards in the posterior mediastinum to the tracheobronchial groups of glands.

TREATMENT

The treatment of this group of cases has been varied according to the general state of the patient, the local condition of the growth and our own experience.

33 of these patients were so ill or so advanced in disease that no treatment other than simple medical care could be offered to them. The hindrance to active measures was not usually age, but the extent of the growth when first seen, the presence of clinically evident secondary deposits, advanced cardiovascular degeneration and concomitant disease in other organs. Of the 67 patients for whom something was attempted, a Souttar's tube was inserted in 14, and radiotherapy given with or without radon in 7. The low proportion treated by radiotherapy has depended upon a number of factors one of which has been the shortage of plant, staff and bed accommodation during the war years. No deductions can be drawn from these patients other than that temporary relief from

on swallowing may occur in gastric or œsophageal lesions respectively, and the latter may come on after the act of swallowing saliva, without food being taken. It is sometimes difficult to decide when a patient has real pain and when he suffers intense annoyance and inconvenience from the impaction of food in the stricture. Severe pain, especially when it radiates into the back, is of evil significance and usually indicates fixation of the growth. This does not necessarily mean that it is irremovable, for involvement of the pancreas can be overcome by the resection of the body or tail of this organ. Sometimes, however, pain in the back would appear to be caused by fixed malignant glands around the cœliac axis. In 2 patients the first symptom was a soreness of the right side of the neck. It is not possible to do more than guess at the explanation of this. Other symptoms that have been noted are heartburn, belching, sometimes with the bringing up of foul-smelling wind, anorexia, hiccough, hæmatemesis and loss of weight. Loss of weight is purposely put last on the list, not because of its infrequent occurrence, but because the emphasis usually placed on this symptom is a potent cause of late recognition of cancer. Hiccough is a relatively rare symptom but it is interesting to note its occurrence in this series. It was complained of in 6 cases. All of these had squamous growths. It was the first symptom in all 6, and the growth was found on œsophagoscopy at 40 to 41 cm. from the alveolar margin in 4, and at 37 cm. in 2.

Physical examination often fails to further the diagnosis and should reveal nothing in the operable case. A tumour in the epigastrium suggests an advanced lesion, while a gland in the neck or mass in the rectum banishes all hope.

The radiography of lesions at the cardia calls for the greatest care, skill and experience if anything but an advanced growth is to be detected. The careful study of the movements, and the mucosal patterns of the œsophagus and stomach in the upright, prone, supine and Trendelenburg positions is necessary. A review of the X-ray appearances of the present series carried out with Dr. A. S. Johnstone, shows that malignant lesions in the lower œsophagus and upper part of the stomach fall into more or less well-defined groups:

A. *Growths Confined to the Œsophagus.*

In these a small length of normal œsophageal mucosa can usually be demonstrated below the growth. They may be subdivided into:—

- (1) Local ulcer.
- (2) Massive tumour: (a) in the lumen and pedunculated; (b) in the lumen and sessile; (c) centrifugal growth with large soft tissue shadow.
- (3) Intermediate group, with new tissue formation and ulceration keeping pace.
- (4) Extensive superficial ulceration.

B. *Growths Occurring at the Gastro-œsophageal Junction.*

These may be œsophageal or gastric in origin, and it is not possible to tell the one from the other by X-ray examination.

C. *Growths Obviously Arising in the Stomach.*

These may be classified into:

- (1) Those giving a picture very like cardiospasm.
- (2) Those showing a horizontal deformity of the abdominal œsophagus.
- (3) Massive carcinoma of the body of the stomach extending up to the cardia.
- (4) Carcinoma of a herniated gastric fundus.

The local ulcer may be missed unless the mucosal pattern is carefully studied; it is most amenable to surgical removal. The massive tumour is not likely to be overlooked. Its recognition as a separate type is useful inasmuch as it may be easily resected in spite of its forbidding appearance. In the pedunculated variety the lumen is seen to be on one side of the mass whereas in the other two the barium passes down the middle of the tumour. The œsophagus which shows extensive superficial ulceration is of pathological interest because it is not uncommon to find islands of ulcerated neoplasm separated from one another by areas of unaffected or leukoplakic mucous membrane. The growths of the stomach which most often cause difficulty in diagnosis are those at the cardia which infiltrate mainly beneath the mucous membrane, and give rise to a picture very like cardiospasm or produce a horizontal deformity of the abdominal œsophagus. These patients are too often treated either by the physician or the endoscopist by repeated blind or œsophagoscopic dilatation. The development of a gastric cancer in the fundus of the stomach which has herniated into the mediastinum has been noted in 5 cases. This may cause difficulty in diagnosis unless the hernia is carefully sought in the Trendelenburg position.

It is worth noting that no case of a small annular malignant stricture at the lower end of the œsophagus has been observed in this series.

The differential diagnosis is mainly to be made from cardiospasm, peptic ulcer of the œsophagus, which has been found fifty times during this period of study, simple tumour,

TECHNIQUE

Pre-operative.—Where possible a good mixed diet is given. When dysphagia is present a high-calorie fluid diet is prescribed, and solids are avoided in order to prevent obstruction and minimize œsophageal irritation above the growth. In this way the fluid content of the body is restored. The blood-count is brought up to normal by transfusion. During the short period of investigation and preparation smoking is prohibited and breathing exercises given to mobilize the chest. Oral infection has been vigorously treated, but it has not been considered necessary to remove teeth as a routine.

Anæsthesia.—After preliminary morphia and scopolamine, sodium pentothal is given into the blood drip. The œsophagoscope is passed and all fluid aspirated. The lower œsophagus is sprayed with penicillin powder and a "Tampax" pack is left in the œsophagus just below the cricoid. Silk thread attached to this is left hanging out of the mouth. Between 9 and 14 c.c. light nupercaine are injected intrathecally when the patient is in position on the right side. The lungs are kept at the required degree of inflation by oxygen given through a face-piece and pharyngeal tube, and unconsciousness is then maintained by nitrous oxide or sodium pentothal as the situation warrants.

Operation.—The approach now used is through the left pleural space after resection of the whole of the 9th rib and cartilage and the posterior end of the 8th. The left phrenic nerve is crushed and local anæsthetic injected into the mediastinum around the œsophagus. The left dome of the diaphragm is split and the extent of the lesion ascertained. The œsophagus above the growth is first mobilized and a fully curved anastomosis clamp applied so that septic fluid cannot escape up the œsophagus from an infected ulcer during the manipulation of the stomach. An effort is made to free the whole area to be removed before the gut is cut, but this has sometimes been impracticable. The stomach is divided and closed first. A second clamp is then applied to the œsophagus above the first, and this is divided after a swab has been placed in the mediastinum behind it. The anastomosis is made between the lower end of the œsophagus and the anterior surface of the stomach. The stomach is then drawn up in front so that the suture line is sunk in a peritoneal cuff. Catgut seems to be quite suitable for the anastomosis but more emphasis must be placed on accuracy of apposition than on materials used. If omentum is available it is wrapped round the junction. Penicillin powder has been applied to the mediastinum in recent cases. The diaphragm is lightly sutured round the stomach and a few interrupted stitches are used to fix the stomach to the diaphragm. The lungs are inflated at intervals during the operation. They are finally inflated when the wound is closed, and an under-water drain inserted. At the end of the operation the œsophagoscope is passed, the pack removed and any fluid or blood aspirated.

Post-operative treatment.—Breathing exercises and frequent changes of positions are prescribed from the first day. Drinks of water or glucose are given in small quantities as soon as the patient wants them. After forty-eight hours tea, milk and dilute fruit drinks are taken, but always washed down with water. After four days, the patient is back on the high-calorie fluid diet including jellies, junket, &c.

The drainage tube is removed after forty-eight hours, and the patient is allowed out of bed on the sixth or seventh day. Aspiration of the chest is carried out as and when required.

REFERENCE

JAMIESON and DOBSON (1907) *Lancet* (i), 1061.

Mr. Ivor Lewis: In cancer of the œsophagus pre-obstructive symptoms are not uncommon. Unfortunately, however, they seldom worry the patient enough to take him to the doctor, and are in any case not likely to suggest the diagnosis. Several of my œsophagectomies have had such symptoms; ensiform pain during swallowing, a cough, hiccups, soreness between spine and scapula. Only in the last-named, however, did the symptoms result in the true cause being diagnosed before obstruction had supervened. *Dysphagia* thus remains the presenting symptom of carcinoma of the œsophagus. It must always be investigated both by X-rays and œsophagoscopy. I agree with Mr. Allison that all cases of cardiospasm must be œsophagoscoped.

A positive biopsy should be the rule before major thoracotomy. In one mid-œsophagus obstruction I had reason to regret this; on thoracotomy no growth could be felt; the chest was closed. On further reference to the section it was highly suggestive only, and should really have raised a serious doubt before deciding on a major exploration. As for the technical problems, I have no experience of presteral œsophagogastrotomy and am interested to hear that Mr. Tanner has abandoned it. For growths of the lower end the one-stage transpleural, transphrenic operation, through the bed of the left 8th rib, should displace all others. The present practice of œsophageal resection is based on the idea of throwing the thoracic and abdominal cavities into one so as to mobilize some part of the abdominal alimentary canal, to secure anastomosis with the œsophagus without

obstruction has been achieved and that it has often seemed worth while. Some operative procedure was attempted on 49 patients. In 11 of these a thoracotomy or laparotomy was done only to find the condition hopeless. In 4 a jejunostomy was done in preparation for a further attack which never materialized. In the early years an attempt was made to obtain relief from obstruction by making a cervical œsophagostomy and connecting this by a rubber tube to a jejunostomy. This was done for 3 patients and then abandoned. At this time also 1 patient was treated by total gastrectomy by the abdominal route, and survived three months. The remaining 30 patients were subjected to a major transthoracic operation, of which 9 were œsophagectomies or œsophago-gastrectomies with a view to extrathoracic reconstruction, 14 œsophago-gastrectomies with mediastinal anastomosis, 2 resections of the whole stomach and lower œsophagus with mediastinal anastomosis between œsophagus and jejunum, and 5 palliative œsophago-enterostomies without resection of growth.

This means that 75 patients in the series were hopeless from the point of view of excision when first seen. The figure is actually worse than this because, of those resected, some were done with the knowledge that the operation could not be considered anything but palliative. The results of surgery cannot be judged on the number of five-year survivals. Obstruction at the cardia causes such discomfort and distress that its relief, even for a few months, is worth achieving, and when a patient has been subjected to a major operation he is entitled to expect some benefit. Nevertheless the aim should be to perform a radical operation where possible, and it is therefore worth while to consider a basis for this which will stand the test of anatomy and physiology and what is known of the pathology of these tumours. The object is in the first place to remove the primary tumour with its area of lymphatic drainage, and secondly to restore continuity of the digestive tract.

It would appear that a radical operation for a growth at the cardia requires the removal of the lower segment of the œsophagus, the fundus and most of the lesser curvature of the stomach, the gastro-hepatic omentum as close to the liver as possible, the left gastric vessels with associated lymphatic glands right back to the cœliac axis, the body and tail of the pancreas and therefore of necessity the splenic vessels and spleen, and as much cellular tissue around the œsophagus as possible at least as far as and including the gland at the level of the inferior pulmonary vein. This formidable undertaking has been the basis of the attack on these tumours during the last few years, and although discretion has been used in its application to particular cases, it seems that a truly radical operation is no worse tolerated than half-measures, by both surgeon and patient alike. A high mortality is more likely to be caused by technical errors involving soiling of the mediastinum or leakage of the anastomosis, than by the slightly increased time and shock involved in the careful dissection of the lymphatic bed.

In the first 9 patients operated upon the growths were excised with a view to an external plastic operation being performed later. All these patients are dead. 3 died from infection following operation, 1 from uræmia eight weeks after operation, 4 from secondary deposits within twelve months and 1 from cardiac failure four years after excision of the growth. A post-mortem examination was obtained in the case of this last patient, and no secondary deposits were present. A plastic operation by skin tube was completed in only 2 cases, 1 of which was the patient who survived and swallowed through her new œsophagus for four years. She was previously shown to this Society.¹ The other died from secondary deposits after twelve months and at autopsy a typical peptic ulcer was found at the junction of skin tube and stomach.

In 14 patients resection with mediastinal anastomosis was carried out, and in one of these the anastomosis had to be performed above the aortic arch on account of the extension of the growth up the œsophagus. Of these, 6 died as a result of the operation, 1 from a leaking anastomosis, 1 from shock, and in this patient malignant glands had to be left around the aorta, 2 from sepsis in mediastinum and pleura, 1 from a fistula at the anastomosis which developed ten days after operation, and 1, the patient in whom the anastomosis was performed above the aorta, from torsion of the stomach and œsophagus on their long axis, causing complete obstruction of the œsophagus. Of the 8 who survived, 3 have already died with secondary deposits, at intervals of nine months, twelve months and fifteen months. The cause of death in the last patient was chronic nephritis but at autopsy small secondary deposits were found in the liver and para-aortic lymph glands. One of these patients developed a peptic ulcer at the anastomosis which responded to dilatation through the œsophagoscope followed by medical measures. There are, therefore, 5 patients still alive and their operations were one, three, three, seven and twenty-four months ago.

Resection of the whole of the stomach and the lower end of the œsophagus was done in 2 patients but in 1 of these the lesion turned out to be a Hodgkin's sarcoma. Both survived the operation, but the one with a very extensive carcinoma died at home three months later. The other is still alive five months after operation but has a mass in the abdomen for which he is receiving X-ray therapy. In this latter case the anastomosis was performed between the œsophagus and a length of intestine mobilized on an elongated mesentery after the method of Roux and recently revived by Yudin. The ability to mobilize such a loop from a thoracic approach raised the possibility of side-tracking irremovable growths and so relieving obstruction. It was urgently necessary to be able to do this in certain cases of peptic ulcer of the œsophagus with almost complete stenosis, and so the method was tried in a few of these advanced growths. In the first case the œsophagus was transected, the stomach end being closed, and the patient died from leakage of the malignant stump. In the next cases the œsophagus was left in continuity and a side-to-side anastomosis performed with the intestine. The first 2 survived and the second 2 both died from infection. Of those who survived, one lived five months in comfort and the other is still alive and standing his turn at the club seven months after operation.

¹Proc. R. Soc. Med., 1943, 36, 143.

(a) *As regards fitness for the operation*, it is often impossible to forecast accurately how a patient will tolerate the anæsthetic, and merely opening the abdomen or thorax or both. Once this has been done, it may be easier to estimate how much more the patient will stand. We have been forced to irradiate some operable tumours because we felt the patient would not tolerate wide resection, or even to abandon cases suitable for direct irradiation because the patient was faring badly. So we very rarely decide beforehand what form of treatment will be carried out, but prepare for all contingencies as far as possible.

(b) *As regards estimating the extent of spread* of the disease, laparotomy is essential, since the spread to lymphatic glands from the lower œsophagus and cardiac area is usually below the diaphragm, mostly to left gastric glands, partly to vasa brevia glands, and partly to pancreatic glands along the splenic vessels. Spread to the posterior mediastinum can be sought for when the thorax is opened. There is some difference of opinion as to when the laparotomy should be done, but it would seem to be unwise and unfair to the patient to open his thorax and divide his diaphragm, before we know the extent of spread in the abdomen.

(i) When there is well-marked œsophageal or cardiac obstruction, *gastrostomy or jejunostomy* may be necessary before the patient's condition can be improved sufficiently to stand the main operation. This can be done through a small upper left paramedian or rectus-splitting incision, through which exploration of the tumour and whole abdomen is possible.

(ii) In other cases, the abdomen can be explored through a similar incision a week or ten days before the main operation, as advocated by Garlock, or immediately preceding this latter as advised by Churchill and Sweet. We have usually followed this latter practice, so as to avoid two operations, but using a different incision more suitable for extension into the thorax.

When the best form of treatment can be decided upon beforehand, there are various methods of approach.

(1) For Resection

(a) *Transsthoracic, transdiaphragmatic approach* without doubt gives a good exposure of, and access to the lower œsophagus and upper stomach. The main principles are the same for all methods, with minor differences in technique as regards choice of level, resection of ribs, division of ribs, &c. The wound is relatively quick to open and close.

(b) *Abdominal approach* alone is usually considered inadequate for cardio-œsophagectomy, due to poor exposure of, and difficult access to, the operation field.

(c) *Two-stage operation* described by Marshall (1938). (i) *First stage* is done from abdomen alone, consisting of mobilization of the stomach with tumour and glands, which are all pushed up into the thorax through the enlarged œsophageal hiatus. (ii) *Second stage* is done from the thorax two weeks later, when the tumour and glands are removed and the anastomosis performed.

Angular abdomino-thoracic incision.—In our early cases, the abdomen was explored through a mid-line incision. When irradiation was decided upon, a transverse incision was made from the upper end of this, through the 6th and 7th left costal cartilages into the 5th space, round to the posterior axillary line. The thorax was opened and the diaphragm split down to the œsophageal hiatus, the incision skirting round the left edge of the pericardium. This gave good access to the cardiac area, though some difficulty was experienced in retracting the angular flap containing the divided left costal margin.

Oblique abdomino-thoracic incision.—In our later cases this difficulty was overcome by exploring the abdomen through an oblique incision across the upper abdomen, from about the 9th right to the 7th left costal cartilages, in line with the outer part of the 5th left interspace. This incision was continued through the left costal margin lower down into the 5th space, the thorax opened and the diaphragm divided as before. This gave a wide straight opening with much better direct access to the whole stomach and lower œsophagus. We have used it for direct irradiation and for surgical excision. But the main disadvantage of both these incisions is the time taken to open and close the wound. When irradiation is carried out considerable time is saved compared with that taken for resection. But then the patient is usually in a worse condition to stand a long operation.

(2) For Direct Irradiation

Due to the tendency of the growth to spread along the stomach or to lymphatics towards the mid-line or beyond, exposure must be made to enable the irradiation to be directed in an antero-posterior plan, otherwise uniform irradiation of the tumour area would be

tension. The stomach is a better organ to use than the small intestine both on account of its remarkable reach—right to the apex of the pleura, and of its indomitable blood supply—never so hazardous as that of a Yudin length of small gut. The stomach should first be made into a bed for the œsophagus to lie on, the bed is firmly sutured to the chest wall before the anastomosis begins.

As for the anastomosis itself, I believe its security depends entirely on the care the surgeon pays to details. It should be end-to-side, using interrupted fine silk sutures, in two layers. The layer most liable to tension is the anterior œsophago-peritoneal. It cannot be too often repeated that in the œsophagus the *mucosa* is the master-layer—just as in the stomach it is the seromuscular layer.

As for the results, the improvement in operative mortality has been remarkable. In 1940, the operation mortality for all the 191 cases of œsophagectomy collected by Ochsner and De Bakey was 72%. I have just heard their figures from three American surgeons—Garlock, Sweet and Phemister. The mortality for their total of 172 operations in the last few years is 29%. Out of 9 cases of this operation in the last five years I have lost 3. We have not yet recovered from the realization of the high malignancy of carcinoma of the œsophagus, but there are two redeeming considerations. First, the survival figures of the above three American surgeons suggest an eventual five-year cure rate of about 10%; secondly, in these latter years of rapid development there is no doubt that surgeons have done resections on a high percentage of cases which were not really operable. This has not only increased the operative mortality but has greatly reduced the proportion of long survivals. But, to say the least, it looks as if the results are going to be appreciably better than in cancer of the stomach.

Mr. Alan Shorter: Diagnosis.—The main accessory aids to diagnosis of carcinoma of the cardia and lower end of the œsophagus are: (i) Radiology; (ii) œsophagoscopy; (iii) gastroscopy.

Space allows me to deal only with radiology which is probably the most useful, but is not free from pitfalls. Special methods enable different diagnostic points to be demonstrated.

(a) *Barium swallow* in the erect position will show the site, type and degree of obstruction and the presence or absence of dilatation of the œsophagus above. This latter occurs to a great degree with carcinomatous obstruction more often than is generally appreciated, while it is usually a marked feature of cardiac achalasia. There the obstruction is not at the cardia but at the diaphragm or above (Calthrop).

(b) *Trendelenburg tilt* of the patient after the barium has entered the stomach will often show distortion or a filling defect of the cardiac stomach on the lesser or greater curvature especially, or of the abdominal œsophagus.

(c) *Retrograde barium meal*, by running barium into the stomach through a gastrostomy tube and then applying the Trendelenburg tilt, will show the cardiac area when the œsophagus is obstructed.

(d) *Air bubble*.—Stewart and Illick, and also Kirklin, stress the importance of examining the air bubble for deformity or the shadow of a soft tissue mass. This is done in the empty or partially barium-filled stomach.

(e) *Air filling*.—Wasch and Epstein have developed a technique of air filling of the stomach, with or without barium, for examining the anterior or posterior walls of the cardiac area. Tumours of these parts will sometimes not be shown by filling the stomach with barium and the Trendelenburg tilt.

Treatment.—At the present time surgery seems to hold out the greatest hope of cure, especially in the early stages. Every case is worth exploring, unless there are clinically obvious widespread metastases or the patient's condition is too poor. Surgical exploration is the only reliable way of deciding the correct form of treatment. Then, and only then, can we decide whether the site and type of tumour and the extent of spread permit of surgical removal, either curative or palliative. Cases rendered inoperable by the poor general condition of the patient or by irremovable local spread, we (Dr. Cranston Fairchild and myself, *Lancet*, October 27, 1945, p. 522) have been treating by a method of Direct Irradiation during the past two years. The object is to irradiate the tumour directly through the open wound, without other viscera or the body wall intervening, thus delivering a more accurate and effective dose of irradiation at high intensity directly to the tumour and field of local spread. We feel that it is more reasonable to irradiate most what most needs irradiating, i.e. the tumour and any local spread, and not the overlying skin and intervening vital tissues or viscera. That is where, in our opinion, external irradiation of visceral cancer fails.

So we feel the choice of treatment lies between Surgical Excision and Direct Irradiation. The problem is how best to decide which is the more suitable method for each individual case.

(a) *As regards fitness for the operation*, it is often impossible to forecast accurately how a patient will tolerate the anæsthetic, and merely opening the abdomen or thorax or both. Once this has been done, it may be easier to estimate how much more the patient will stand. We have been forced to irradiate some operable tumours because we felt the patient would not tolerate wide resection, or even to abandon cases suitable for direct irradiation because the patient was faring badly. So we very rarely decide beforehand what form of treatment will be carried out, but prepare for all contingencies as far as possible.

(b) *As regards estimating the extent of spread* of the disease, laparotomy is essential, since the spread to lymphatic glands from the lower œsophagus and cardiac area is usually below the diaphragm, mostly to left gastric glands, partly to vasa brevia glands, and partly to pancreatic glands along the splenic vessels. Spread to the posterior mediastinum can be sought for when the thorax is opened. There is some difference of opinion as to when the laparotomy should be done, but it would seem to be unwise and unfair to the patient to open his thorax and divide his diaphragm, before we know the extent of spread in the abdomen.

(i) When there is well-marked œsophageal or cardiac obstruction, *gastrostomy* or *jejunostomy* may be necessary before the patient's condition can be improved sufficiently to stand the main operation. This can be done through a small upper left paramedian or rectus-splitting incision, through which exploration of the tumour and whole abdomen is possible.

(ii) In other cases, the abdomen can be explored through a similar incision a week or ten days before the main operation, as advocated by Garlock, or immediately preceding this latter as advised by Churchill and Sweet. We have usually followed this latter practice, so as to avoid two operations, but using a different incision more suitable for extension into the thorax.

When the best form of treatment can be decided upon beforehand, there are various methods of approach.

(1) For Resection

(a) *Trans thoracic, transdiaphragmatic approach* without doubt gives a good exposure of, and access to the lower œsophagus and upper stomach. The main principles are the same for all methods, with minor differences in technique as regards choice of level, resection of ribs, division of ribs, &c. The wound is relatively quick to open and close.

(b) *Abdominal approach* alone is usually considered inadequate for cardio-œsophagectomy, due to poor exposure of, and difficult access to, the operation field.

(c) *Two-stage operation* described by Marshall (1938). (i) *First stage* is done from abdomen alone, consisting of mobilization of the stomach with tumour and glands, which are all pushed up into the thorax through the enlarged œsophageal hiatus. (ii) *Second stage* is done from the thorax two weeks later, when the tumour and glands are removed and the anastomosis performed.

Angular abdomino-thoracic incision.—In our early cases, the abdomen was explored through a mid-line incision. When irradiation was decided upon, a transverse incision was made from the upper end of this, through the 6th and 7th left costal cartilages into the 5th space, round to the posterior axillary line. The thorax was opened and the diaphragm split down to the œsophageal hiatus, the incision skirting round the left edge of the pericardium. This gave good access to the cardiac area, though some difficulty was experienced in retracting the angular flap containing the divided left costal margin.

Oblique abdomino-thoracic incision.—In our later cases this difficulty was over come by exploring the abdomen through an oblique incision across the upper abdomen, from about the 9th right to the 7th left costal cartilages, in line with the outer part of the 5th left interspace. This incision was continued through the left costal margin lower down into the 5th space, the thorax opened and the diaphragm divided as before. This gave a wide straight opening with much better direct access to the whole stomach and lower œsophagus. We have used it for direct irradiation and for surgical excision. But the main disadvantage of both these incisions is the time taken to open and close the wound. When irradiation is carried out considerable time is saved compared with that taken for resection. But then the patient is usually in a worse condition to stand a long operation.

(2) For Direct Irradiation

Due to the tendency of the growth to spread along the stomach or to lymphatics towards the mid-line or beyond, exposure must be made to enable the irradiation to be directed in an antero-posterior plan, otherwise uniform irradiation of the tumour area would be

impossible. Therefore the left transthoracic approach is unsuitable for direct irradiation of these tumours.

Post-operative reactions have been no more severe than would have been expected after the operation alone, even after a maximum tumour dose of over 1,500 r in three minutes.

CASE I.—Male, aged 35. Carcinoma of lesser curve, 13 cm. long by 7 cm. antero-posteriorly by 4.5 cm. thick. Alive two years after direct irradiation.

CASE II.—Female, aged 57. Carcinoma of abdominal œsophagus 5 cm. long by 2.5 cm. wide. Lived fifteen months after direct irradiation, then died of bronchopneumonia and cirrhosis of the liver. No growth was found in treated area but a few deposits were found at base of right lung.

Mr. Donald Barlow said that he had carried out ten resections of the lower end of the œsophagus with or without the stomach, and of these, four were still alive and well. One was for a simple stricture but all the others were for carcinoma.

He had found that especially in those cases where it was necessary to prepare a jejunal loop for anastomosis to the œsophagus, as, for instance, where most of the stomach was infiltrated by growth, the best exposure could be obtained by resection of the 10th rib on the left side perhaps with division of the posterior end of the 9th. This was an entirely new approach but it had three great advantages:

(i) Only the lower part of the incision need be made in the first place so that operability of the growth could be assessed before opening the chest and diaphragm.

(ii) As pointed out by Mr. Allison, resection of carcinoma of the stomach or œsophagus must include block dissection of all lymphatics and glands likely to be infiltrated. Those on the splenic artery and pancreas and around the pylorus, &c., were most important and in several of the speaker's cases not only the spleen and peritoneum on the posterior wall of the lesser sac but also the splenic artery and part of the pancreas had been removed. This exposure greatly facilitated this manoeuvre.

(iii) The preparation of jejunal loop after the manner of Yudin was made much easier and the arterial arcades could easily be transilluminated.

Whereas in one of the speaker's cases it had been possible by mobilizing the duodenum to bring it up into the chest to effect a direct œsophageal anastomosis, he had to prepare jejunal loops in three others. One of these patients was still alive and well. In another case in which it had been necessary to leave the distal two inches rather blue in order to get enough length, the operation was done in two stages, the loop being left below the diaphragm. When a week later the chest was opened to resect the œsophageal growth, the loop could not be found without opening the abdomen through a paramedian incision and the loop was discovered at the bottom of the pelvis with three inches of the distal end gangrenous. The surviving part of the jejunum had to be brought out subcutaneously and the upper end of the œsophagus through the neck. He had found in the third case where it was also necessary to leave the distal two inches of jejunum blue, that by bringing the loop subcutaneously at the first stage of the operation, it survived because it derived some additional blood supply from the tissues in which it was embedded. If desired he thought it might be possible at the second stage of the operation to remove the jejunum from its subcutaneous bed and bring it up through the diaphragm if its proximal end had already been threaded through the transverse meso-colon and up behind the stomach through the lesser omentum.

Mr. Barlow thought that a preliminary gastrostomy interfered with the operation and disagreed with another speaker that the phrenic nerve should not be crushed following an anastomosis in the chest because it was necessary to suture the stomach or jejunum to the opening in the diaphragm and unless this were done there would be drag on the anastomosis which would endanger its safety.

He considered it was quite useless to irradiate adenocarcinomas and failed to understand Mr. Tanner when he spoke of postural drainage for the treatment of pulmonary œdema. The speaker had found that where the patient was well enough, postural drainage might be useful where a lobe was atelectatic but in most instances it was advisable to pass a bronchoscope immediately and aspirate the bronchial contents, since failure to do this might result in many deaths.

[January 3, 1946]

DISCUSSION ON CORTICAL ATROPHY

Mr. Harvey Jackson: The literature on the subject of cortical atrophy is disappointingly sparse. Certainly one would not do justice to this discourse without including those atrophic states of the cortex that accompany atrophy of subjacent white matter. Thus any condition attended by shrinkage of cortical tissue claims significance and warrants inclusion.

In referring to cortical atrophy two different forms of morbid anatomy come to mind. The one produces constriction of the affected gyri whilst the intervening sulci deepen and widen. The appearance of the cortex thereby resembles that of a shelled walnut enveloped in a fluid sac—appearances suggesting the terms “walnut brain” and “wet brain” as most appropriate designations. The second type of atrophic change is to be found incorporated with disease in the white matter. The gyri are flattened on the surface, widened transversely, but attenuated in depth of grey matter—well demonstrated in association with porencephalic cysts.

From the point of view of the neurosurgeon, the scope is perhaps more restricted, for, in so far as his practice is concerned, the effects of injury and the differentiation between tumour-formation and clinical states simulating tumour-formation are the main deliberations. Indeed the clinical material from which my cases are derived provides a number in which the precise pathological diagnosis of meningioma has brought me into the therapeutic programme.

Before discussing any of the more intimate details of particular lesions a more generalized citation of the many factors in causation is warranted. The order in which the various types of lesion are to be discussed has no application to their relative incidence; in fact some stress will be made of less common, though less frequently, recognized states.

Perhaps I may refer somewhat speculatively, and with trepidation, to the systematized atrophies, not without the full realization that the primary disorder may be a demyelinating process in deference to an atrophic state. It cannot be denied that such conditions as Schilder's disease and atrophy of the Pick, or Alzheimer type, occasionally stray into the hands of the neurosurgeon either because the true nature of the disease is missed in its early phase, or because of a less typical form of onset. In Schilder's disease the onset may be suggestive of a focal lesion and this can be accompanied by papilloedema. In so far as the generalized atrophies are concerned—patients are sometimes admitted in stuporose or semicomatose states. Under these circumstances, suspicion of the presence of a subdural hæmatoma may determine the surgeon into making exploratory burr holes.

The surgeon is ever mindful of the effects of injury, and is only too well aware of the possibility of diffused damage in addition to local injury. Moreover the initiation of diffuse changes from both closed and open injuries is appreciated. Strangely enough, while the dire effects of repeated head injury gain recognition the practical implication of this knowledge sometimes fails: the occurrence of atrophic changes in the brain originating from the occupation of boxing is well recognized, yet the extensive cortical atrophy that develops from the oft-repeated convulsive treatment, applied by psychiatrists to the relief of depression and other mental disorders, is ignored.

When talking of injury mechanical disruption of structure is the usual inference, but it must not be forgotten that other physical agents can be responsible. In particular I refer to X-rays. Occasionally one sees very extensive atrophic changes in the brain brought about by the application of intensive deep therapy for a cerebral tumour. The atrophy is of a very protracted onset, hence it is not to be seen with the more malignant gliomata owing to the short duration of life afforded by these neoplasms. It may be a matter of five years or more before the change materializes.

Those lesions thus far discussed have been of such a nature as to involve a number of gyri even when described as "localized" This by no means excludes the feasibility of an atrophic state applied to a portion of a gyrus. Doubtless an injury may be so restricted in effect, but the lesions to which I am about to refer are of other causation. They are the results of infection or of vascular disturbance of one form or another. Those infections most prone to produce what one supposes to be limited zones of "encephalitis" are the specific fevers—one has seen lesions that had arisen during the course of measles, whooping-cough, influenza, dysentery, tonsillitis, scarlet fever, pneumonia, &c. Patients who have been so afflicted seek advice on account of and relief from epileptiform manifestations, either focal or general. Unfortunately the import of infection in the clinical history may fail to gain recognition, and in consequence a patient may be submitted to an unnecessary exploratory operation. Similar patches of localized atrophy sometimes result from thrombosis of a cortical vein—a complication occasionally seen during pregnancy, or during the puerperium. Other forms of atrophic lesions are to be encountered, forms arising out of pathological vascular states. The diffuse cerebral atrophy of senile dementias consequent on chronic cerebrovascular disease is well recognized. A less heeded form of atrophy, vascular in origin, is that produced as the result of an arteriovenous fistula. Just how this takes effect is not established, but the anoxemic state of the blood is a probable factor. The mention of a vascular fistula reminds one that the large arteries which supply the brain can be directly involved in other ways, even in their extracranial course; an injury to the internal carotid artery in the neck has been known to cause extensive atrophic changes in the brain.

Omission of those peculiar atrophic states of the cortex to be found in babies, so beautifully depicted in an article by Ingraham and Matson (1944) under the title of "Subdural Hæmatoma in Infancy", would leave our discussion incomplete. The cortex in some of these cases shows an extraordinary state of formation of the affected area—this is described in that article as consequent on hæmatoma formation. How this change could be produced by the compression induced by a subdural hæmatoma is difficult of explanation. The pathology is obscure. In my opinion the state of the brain in some cases at least is more likely to result from structural defect of developmental origin. The frontal lobes and the parietal lobe, and the paracentral lobule in particular, seem to be sites of predilection (figs. 1 and 2).

FIG. 1.—Excessive quantities of air distributed over the frontal and parietal regions. A gross degree of cortical agensis.

FIG. 2.—Air over the surface of the parietal lobe of a baby indicating a restricted degree of agensis.

What are the clinical aspects of these several different conditions? Obviously the resultant disturbances are in some degree to be correlated with the particular regions of the brain involved. Nevertheless diffuse atrophic changes can occur without giving rise to localizing evidence manifest on neurological examination. The incidence of

epileptiform phenomena is very high—in something like 75% of all cases. Generalized convulsions occur, from frontal lesions in particular; Jacksonian attacks associate themselves with Rolandic lesions. Focal attacks appear to originate more commonly from the limited patches of encephalitis brought about by localized infection or circumscribed vascular thrombosis.

Whatever the form of the attack, in typical cases of cortical atrophy the history has proved generally to be a protracted one of several years' duration. A carefully elicited history should reveal any possible underlying infection, injury, or thrombosis recognizable as the exciting factor. When focal attacks have occurred over a number of years and then, on examination, neurological signs are judged to be static, tumour is unlikely. Should the neurological signs prove the lesion to be extensive, in terms of cortical implication, then, in the absence of symptoms and signs of intracranial pressure, the diagnosis of tumour would be improbable. Moreover the clinical state is often of a character that is difficult of explanation on a tumour basis; a poor mentality is not an uncommon finding, pyramidal signs are frequently accompanied by reduced sensory perception in one form or another, and in about 25% of my personal cases a visual field defect has been present.

Headache is a complaint in about 50% of cases but it bears hypotensive qualities as a rule, therefore it is unlikely to be mistaken for the headache of increased intracranial pressure.

Vomiting has not played any part in the clinical stories available.

Ultimately we reach the stage where a relatively circumscribed area of cortical atrophy becomes more or less indistinguishable from the development of a cerebral tumour, especially a meningioma. The history is that of a prolonged story of epileptiform attacks, periods of years not being unusual. The attacks are of focal or Jacksonian nature, usually to be followed sooner or later by paresis in one limb, and perhaps later still by hemiparesis. Indeed the whole story is that commonly supposed to characterize tumour-formation. Headache may, or may not, occur. Under these circumstances one may ask if a clinical differentiation between tumour and atrophy is to be reached. Personally I believe that such a differentiation is possible, but I would not care to base treatment on clinical evidence alone. Confirmatory evidence is not only advantageous, it is essential.

How then may this differentiation be formulated? In the first place one should keep the possibility of cortical atrophy in mind when a history of epilepsy of several years' standing is presented by an adult patient. The age-incidence is by no means restricted, although the majority of cases in my experience have been between 30 and 50 years of age. Evidence of a tendency to neurofibromatosis is usually lacking in atrophy, whereas it is not infrequent in a patient harbouring a meningioma. In what one considers to be a typical patient the blood-pressure tends to be on the low side of normal. Mentally these patients tend to be intellectually dull with poor memories and reduced powers of concentration should the atrophy be widely distributed. The optic discs most often are normal, visual acuity is normal, but field defects are surprisingly frequent. Usually the optic discs are within normal limits of appearance. However, on occasion one sees a peculiar moistness to be likened to that of the sclera and eyelids after weeping—an appearance aptly described as a "wet disc". The apparent swelling is not usually measurable.

Pathological investigation.—Lumbar puncture: Generally the manometric pressure of the cerebrospinal fluid is subnormal. Total protein and cell contents are normal. Wassermann reaction is negative. X-rays show no change.

Radiographic examination.—Plain X-rays so far as I am aware, cannot be said to show any characteristic appearances. Over and over again, however, I have been impressed by the rather exuberant pattern of the diploëic vascular channels in these cases. These vascular markings can be misleading for they may be incorrectly interpreted as supportive evidence of that adventitious vascularization we recognize as occurring in the presence of a meningioma.

Curiously enough the incidence of calcification in intracranial structures, e.g. pineal gland, choroid plexuses, and the falx, is greater than that occurring in normal patients of corresponding ages. Should any displacement of such shadows be recognizable, the displacement is towards the side of the lesion.

Owing to irregularities of bony density and occasionally from calcific deposits on the dura mater, one may observe a shadow, a shadow that may be acceptable as a hyperostosis, thereby being taken to confirm a diagnosis of suspected meningioma, whereas in fact no actual tumour is in existence. Careful elucidation of the nature of shadows of this type will necessitate stereoscopic films (figs. 3 and 4).

Even with the most careful study of radiographs it is obvious that mistakes can still be made. How then should one confirm the diagnosis? Contrast radiography by air

FIG. 3.

FIG. 3.—Patch of rarefaction (indicated by arrow) in the parietal region associated with subjacent cortical atrophy.

FIG. 4.

FIG. 4.—Bony irregularity (indicated by arrow) in the frontal region likely to be mistaken for a hyperostosis associated with meningioma formation. Note exuberant pattern of vascular channels.

FIG. 5.

FIG. 6.

FIG. 6.—Visualization of the third ventricle on lateral view—considered to be incompatible with a normal brain.

encephalography or ventriculography usually proves conclusive. On carrying out such forms of investigation one may be astounded at the extent of the abnormality so envisaged.

Gross defects in radiographic appearances are easy enough to interpret, but just how much alteration in an X-ray is essential to confirm the presence of atrophy is uncertain. Estimations of the relative capacities of the ventricles and the subarachnoid spaces, up to now, have been rather conjectural, being formulated on previous observations extended over numerous cases. Impressions have led me to believe that accumulations of air over the parietal cortex are evidence of abnormality, especially if the exposures are made with the patient in a horizontal posture. Likewise visualization of the outline of the third ventricle on a lateral view is not to be seen in the undilated ventricle on the exposures ordinarily employed (figs. 5 and 6).

Evans (1942), in a recent paper, reports an investigation into the relationship between the transverse diameter of the anterior horns and internal diameter of the skull. Judging from his figures it seems that a ratio of not less than 1 : 3 must be looked upon as within normal limits.

Electro-encephalography in its present form does little more than indicate an abnormality, more often than not of wide distribution; sometimes lateralizing changes are available. According to Trowbridge and Finlay (1942), normal E.E.G. tracings may be found in cases showing only cortical atrophy, but are not found in cases with dilated ventricles.

Dr. John J. Fleminger: During the years of this last war a diagnosis of cortical atrophy was made in 71 cases admitted to a neurosurgical unit for investigation. 31 of these were infants, and of the remaining adults, 28 were sent in by neurologists, all with a clinical diagnosis of cerebral tumour. Among these 28 cases there is a short series which appears to stand apart from the rest. In selecting these I have excluded all those cases in which there was anything in the history or on examination which might have pointed to a cortical degeneration, so that no case was included which gave any history of head injury, recent infection or with hypertension or arteriosclerosis, or was over the age of 60. This has left 12 cases, which appear to be examples of a cerebral atrophy of unknown cause, presenting clinically as cerebral tumours, and probably allied in pathology to the pre-senile dementias, but differing from these in that dementia is not found.

These cases consist of adults between the ages of 27 and 57 with an average age of 45. 8 were men and 4 were women. The commonest clinical diagnosis made was of a slowly-growing benign tumour, most frequently meningioma. In none was there anything to suggest any alternative pathology, and it was only on further investigation that the true nature of the condition was discovered.

There were certain very definite negative findings common to all of them. These were: normal fundi with normal optic discs, normal cerebrospinal fluid and fluid pressures, negative W.R.s, and the absence of any form of mental change suggesting dementia. In every case the blood-pressure was normal or low, and in no instance was there any bradycardia. Nausea and vomiting did not occur in any case. There was also no history of concussion or any other kind of craniocerebral injury as these cases had been excluded.

The most important symptoms were.—Epilepsy of all varieties, both major attacks and focal fits, motor and sensory; transient attacks of uselessness of a limb leading to paralysis; dysphasia, almost exclusively of the expressive kind; severe headaches and attacks of dizziness. When memory defect occurred, which was seldom, it was always associated with some degree of dysphasia.

Among the physical findings, loss of power in limbs was unilateral in every instance and the hemipareses were flaccid in only two cases; sensory impairment was less frequently found, but was most characteristically a loss of position sense. Ocular palsies and visual defects only occurred in 2 cases and homonymous hemianopia in one of these.

Straight X-rays of the skull revealed no constant or prominent abnormal features. In some the vessel markings over the vault were rather more evident than normal, and in one case, there was an area of irregular calcification corresponding to degeneration of the hemisphere discovered at craniotomy.

Electro-encephalography was done in only two of the cases. In both of these there was an abnormal focus in the region of maximum atrophy and in one, performed on a man with a left hemiparesis, the E.E.G. suggested a diffuse cortical dysfunction in both hemispheres, but most predominantly in the right frontal region. From these two cases alone it is obviously impossible to draw any conclusion as to the value of E.E.G. in the differentiation of this condition from tumour.

The discovery of cortical, or at least cerebral, atrophy was ultimately made by air studies or by craniotomy and direct inspection. A ventriculography was performed in each case, and some also had lumbar or cisternal encephalograms. The characteristic features of atrophy, as shown by air studies, in these cases were dilatation of the ventricles either bilaterally or unilaterally without any shift of the ventricular system, and, more striking, the increased convolutional marking of air in the subarachnoid space revealing the widened sulci, as seen in encephalograms. This was best seen over the vertex when the patient was X-rayed in the sitting position. Subdural puddles of air at the frontal and occipital poles and down the side of the falx were frequently seen, and were sometimes seen in the temporal region, in ventriculograms. In this connexion one should mention the increase in depth of the subdural space and the lax, sometimes wrinkled dura, found when the burr hole for ventriculography has been made, which were often the first indications that one was not dealing with a space-occupying lesion. One important fact is that although the physical signs and the symptoms may point to only a local cortical lesion, and in fact there may only be a unilateral ventricular dilatation, this is not always the case, and frequently the area of atrophy as demonstrated by air studies is seen to extend over a wide distribution and often to the opposite hemisphere.

The characteristic appearance of the surface of the cerebral cortex at craniotomy was a deep subarachnoid space bridging over widened sulci filled with excess of C.S.F. under low pressure. These sulci frequently, but not invariably, contained large thickened and tortuous blood-vessels. The cortex is described as being more rubbery and harder than usual to the touch and the convolutions appear shrunken and narrow. 4 of these cases had craniotomies, all performed by Mr. Wylie McKissock, and all presented a similar appearance, and also appeared to be macroscopically identical with other cases of atrophy of known cause.

The following are brief summaries of three of these cases which demonstrate some of the more typical features.

CASE I.—Man, aged 40. Admitted January 1946 with a six months' history, beginning with attacks of pins and needles in his left foot and weakness of his left hand. He was treated for rheumatism until he became so paralysed that he was unable to get about. He also complained of frontal headaches. He had a left lower facial palsy and a flaccid paresis of his left arm and leg without sensory loss. His ventriculograms showed dilatation of the whole of the right lateral ventricle compared with the left and increased convolutional markings over the cortex, particularly in the right frontal region, showing the maximum atrophic change to be in this area (fig. 1).

CASE II.—Woman, aged 56. She had a gradually increasing hemiplegia for two years, starting in the right foot and spreading upwards to involve the right arm. She complained of severe frontal headache. A diagnosis had been made of left frontal meningioma. Her ventriculograms showed dilatation of the left lateral ventricle compared with the right. A craniotomy was performed. A left fronto-parietal flap was turned down, and the typical appearances of shrunken atrophic brain were seen, maximum at the upper ends of the motor-sensory cortex. Now, five years later, this woman is still alive, moderately well, but has developed a severe spastic paraplegia.

CASE III.—Man, aged 27. Had major epilepsy for two years. A diagnosis of right frontal meningioma had been made; E.E.G. showed a right frontal focus of slow irregular delta waves. His encephalogram pictures showed increased convolutional markings in the frontal region. At operation marked atrophy was revealed in the right frontal region and unusually large and tortuous venous channels were seen (fig. 2). A year after he was discharged, he had shown no deterioration and his fits were being controlled by luminal.

The value of encephalography in this condition is demonstrated in figs. 3, 4, 5 and 6. They are of a man with aphasia and right hemiplegia. Ventriculograms, figs. 3 and 5, first showed dilatation of the left lateral ventricle. Then lumbar encephalography performed

FIG. 1.

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 2.

JOHN J. FLEMINGER: Cortical Atrophy.

FIG. 6.

about a week later revealed the condition of the surface of the cortex with the widened convolutional markings far more evident on the left than on the right, figs. 4 and 6.

The only light which can be thrown on the pathology of this condition from these few cases, is the report on a small biopsy that was taken from the cortex and underlying white matter at the operation on a man aged 37 with aphasia and right hemiplegia. As one cannot lay any stress upon an individual case, this does not contribute much to a discussion on ætiology; here, however, is a short summary of the report:

"Cortical degeneration and sclerosis of unknown ætiology. Two areas of scarring in the cortex in close proximity to blood-vessels. The nerve cells show marked swelling of the nucleus in many cases; others, however, are shrunken and dark staining with corkscrew apical dendrites, these cells being clearly in the process of chronic degeneration. The white matter showed increased gliosis with much perivascular hæmorrhage." The neuropathologists who saw the sections were unable to classify the nature of these changes.

SUMMARY

This has been an attempt to present a few cases which do appear to stand apart from other types of cerebral atrophy, at least in the way in which they are presented to the physician. That is, as a condition affecting adults of middle years with a symptomatology closely resembling a slowly growing cerebral tumour. The most important points which may assist in a clinical differentiation seem to be—the absence of papilloedema, bradycardia or vomiting even in very advanced cases. The ultimate distinction and diagnosis can only be made with certainty by air studies or craniotomy. As far as prognosis is concerned, only one of the 12 cases has, to my knowledge, died, but the follow-ups are too short for any really helpful conclusions to be drawn at this stage.

I have been unable to find any reference in the literature which bears directly on these cases.

Finally, I would like to express my gratitude to Mr. Wylie McKissock who has given me so much kind assistance.

[February 25, 1946]

Unilateral Hyperplasia of the Mandibular Condyle

By MARTIN A. RUSHTON, M.B., L.D.S.

HYPERPLASIA of the mandibular condyle on one side only appears first to have been described by Adams before the Medical Section of the British Association in 1836 (Adams, 1873) as a manifestation of rheumatoid arthritis. Humphry (1856), Eve (1883) and Heath (1883) described further cases, and small numbers have been added by other authors from time to time. Surveys of reported cases then known were made by Heath (1884), Perthes (1907) and others, the most recent accessible to me being that of Gruca and Meisels (1926). By that time about 17 cases were known; and since then further examples have been reported by Ivy (1927), Dufourmentel (1927), Thoma (1945), and others. It may now be possible to add a little to the survey of Gruca and Meisels; and I am able to describe a few new cases.

CASE I.—The patient was a healthy soldier of 28 who complained of discomfort in the right temporomandibular joint (fig. 1). Spontaneous dislocation of the mandible began to occur there one year before; and when seen it happened every time the jaw

FIG. 1.

FIG. 2.

was opened and became reduced spontaneously on closing. Most of the usual signs of unilateral condylar hyperplasia were present: elongation of the ascending ramus on that side, and enlargement of the condylar neck and head but not of the coronoid process (fig. 2). There was an open bite of the cheek teeth on the same side and an

about a week later revealed the condition of the surface of the cortex with the widened convolutional markings far more evident on the left than on the right, figs. 4 and 6.

The only light which can be thrown on the pathology of this condition from these few cases, is the report on a small biopsy that was taken from the cortex and underlying white matter at the operation on a man aged 37 with aphasia and right hemiplegia. As one cannot lay any stress upon an individual case, this does not contribute much to a discussion on ætiology; here, however, is a short summary of the report:

"Cortical degeneration and sclerosis of unknown ætiology. Two areas of scarring in the cortex in close proximity to blood-vessels. The nerve cells show marked swelling of the nucleus in many cases; others, however, are shrunken and dark staining with corkscrew apical dendrites, these cells being clearly in the process of chronic degeneration. The white matter showed increased gliosis with much perivascular hæmorrhage." The neuropathologists who saw the sections were unable to classify the nature of these changes.

SUMMARY

This has been an attempt to present a few cases which do appear to stand apart from other types of cerebral atrophy, at least in the way in which they are presented to the physician. That is, as a condition affecting adults of middle years with a symptomatology closely resembling a slowly growing cerebral tumour. The most important points which may assist in a clinical differentiation seem to be—the absence of papilloedema, bradycardia or vomiting even in very advanced cases. The ultimate distinction and diagnosis can only be made with certainty by air studies or craniotomy. As far as prognosis is concerned, only one of the 12 cases has, to my knowledge, died, but the follow-ups are too short for any really helpful conclusions to be drawn at this stage.

I have been unable to find any reference in the literature which bears directly on these cases.

Finally, I would like to express my gratitude to Mr. Wylie McKissock who has given me so much kind assistance.

main cartilage mass. The activity in the precartilaginous layer appears to regulate the rate at which the condyle and the condylar neck (which is formed from the condyle by remodelling) will grow. At about the age of 20 the formation of cartilage from precartilaginous tissue normally ceases and the replacement of cartilage by bone gradually stops also. The marrow cavity is now entirely shut off from the remains of the cartilage by a closing plate of bone. An inactive remnant of the precartilaginous layer persists, and might be stimulated to activity once more in certain circumstances, for example in acromegaly (figs. 3 and 4).

The sections of this abnormal case showed that the precartilaginous layer is in some parts of great thickness, at others less so, but apparently producing cartilage cells everywhere at its lower border. The cartilage itself is in parts very thick, and it is everywhere being actively eroded and replaced by new bone (fig. 5). Islands of cartilage can be recognized nearly 1 cm. below the main cartilage mass. The condyle was therefore in a state not only of active but also of irregular growth; and we may say that its excision has not merely cured the complaint but prevented the development of a more severe deformity later.

CASE II.—The following case was kindly referred to me by Mr. G. J. Parfitt and Mr. A. McLeod. The patient was a soldier of 36 who complained solely of the asymmetrical appearance of his face (fig. 6). The chin was projecting to the right and forwards and the vertical dimension of the mandibular ascending ramus on the left was abnormally great. The few remaining lower teeth on the right had come to occlude outside the upper teeth, and the left lower canine tooth lay just beneath the left upper central incisor. The appearance suggested that the whole lower jaw had been projected forward from the left condylar region. Movement was full and free. Radiographs showed that there was an enormous increase in the length of the left condylar process and increase in the size of the left condyle (fig. 7). The left coronoid process was no larger than normal and hence appeared relatively very short.

FIG. 6.

FIG. 7.

Asymmetry was first noticed at the age of 16, and it continued to increase, he thinks, until two years ago after which no change was noticed. He has never had a discharging ear or, according to him, any other illness. He started boxing at 15 and this became his principal interest.

It was decided to resect about 1½ in. from the left condylar region, leaving a false joint. This operation was performed by Mr. J. B. Cuthbert through the post-auricular approach, the enlarged condyle being removed after cutting through the rather soft condylar neck, and a portion of the latter also resected. It immediately became possible to restore the chin to near the mid-line and to reduce its prominence, so that the right lower incisors now occluded inside the upper. No fixation other than a bandage was used, and the latter was removed for meals after the third day, movement being encouraged. In two weeks a partial lower artificial denture was provided and the patient was discharged. Movements were painless and free but not completely full, and function was good. The improvement in appearance from the front was considerable, that of the profile very satisfactory indeed (fig. 8).

The secondary changes which occur in the mandible in the course of years as a result of condylar overgrowth are such that removal of the condyle cannot be expected to restore complete symmetry in an advanced case.

The condyle removed was of more than twice normal thickness but near normal width, and thus rather globular. Many small islands of calcified cartilage were present in the bone trabeculae. There was quite a thick layer of cartilage present on part of the articular

overclosed shearing bite on the other. The mandible was obviously tilted about an antero-posterior axis, but there was little deviation of the chin, probably owing to the deep incisor overbite. No history or signs of injury, or of middle ear or other disease could be obtained. Discomfort was immediately relieved by excision of the condyle (Dr. J. Converse).

Before describing the results of histological examination I shall describe the normal condition. During the period of growth the articular surface of the condyle is covered with fibrous tissue as Hertwig first pointed out (1892). Beneath this is a layer of pre-cartilaginous connective tissue, and it is from this that the next layer, of cartilage, is progressively formed. The cartilage becomes calcified at its lower part and is there eroded into bays continuous with the marrow cavity of the bone; and bone is deposited on, in, and around it. The older the individual the less cartilage islands can be found in the bone of the ramus; at birth they can be found at least as far down as the mandibular foramen, but at 16 years they will only be found a few millimetres from the

FIG. 3.—Normal condyle. Diagram of section at 16½ years. F, fibrous layer; P, precartilaginous layer; C, cartilage; bone black.

FIG. 4.—Normal condyle. Diagram of section at 21 years. A continuous bony plate has formed beneath the articular surface (Figs. 3 and 4 from *Brit. Dent. J.*, 1944, 76, 60).

FIG. 5.—Stained picrothionin. $\times 50$. Precartilaginous tissue above; thick layer of cartilage (black); line of erosion bays; and beneath, numerous bone trabeculae (grey) containing much cartilage (black).

main cartilage mass. The activity in the precartilaginous layer appears to regulate the rate at which the condyle and the condylar neck (which is formed from the condyle by remodelling) will grow. At about the age of 20 the formation of cartilage from precartilaginous tissue normally ceases and the replacement of cartilage by bone gradually stops also. The marrow cavity is now entirely shut off from the remains of the cartilage by a closing plate of bone. An inactive remnant of the precartilaginous layer persists, and might be stimulated to activity once more in certain circumstances, for example in acromegaly (figs. 3 and 4).

The sections of this abnormal case showed that the precartilaginous layer is in some parts of great thickness, at others less so, but apparently producing cartilage cells everywhere at its lower border. The cartilage itself is in parts very thick, and it is everywhere being actively eroded and replaced by new bone (fig. 5). Islands of cartilage can be recognized nearly 1 cm. below the main cartilage mass. The condyle was therefore in a state not only of active but also of irregular growth; and we may say that its excision has not merely cured the complaint but prevented the development of a more severe deformity later.

CASE II.—The following case was kindly referred to me by Mr. G. J. Parfitt and Mr. A. McLeod. The patient was a soldier of 36 who complained solely of the asymmetrical appearance of his face (fig. 6). The chin was projecting to the right and forwards and the vertical dimension of the mandibular ascending ramus on the left was abnormally great. The few remaining lower teeth on the right had come to occlude outside the upper teeth, and the left lower canine tooth lay just beneath the left upper central incisor. The appearance suggested that the whole lower jaw had been projected forward from the left condylar region. Movement was full and free. Radiographs showed that there was an enormous increase in the length of the left condylar process and increase in the size of the left condyle (fig. 7). The left coronoid process was no larger than normal and hence appeared relatively very short.

FIG. 6.

FIG. 7.

Asymmetry was first noticed at the age of 16, and it continued to increase, he thinks, until two years ago after which no change was noticed. He has never had a discharging ear or, according to him, any other illness. He started boxing at 15 and this became his principal interest.

It was decided to resect about 1½ in. from the left condylar region, leaving a false joint. This operation was performed by Mr. J. B. Cuthbert through the post-auricular approach, the enlarged condyle being removed after cutting through the rather soft condylar neck, and a portion of the latter also resected. It immediately became possible to restore the chin to near the mid-line and to reduce its prominence, so that the right lower incisors now occluded inside the upper. No fixation other than a bandage was used, and the latter was removed for meals after the third day, movement being encouraged. In two weeks a partial lower artificial denture was provided and the patient was discharged. Movements were painless and free but not completely full, and function was good. The improvement in appearance from the front was considerable, that of the profile very satisfactory indeed (fig. 8).

The secondary changes which occur in the mandible in the course of years as a result of condylar overgrowth are such that removal of the condyle cannot be expected to restore complete symmetry in an advanced case.

The condyle removed was of more than twice normal thickness but near normal width, and thus rather globular. Many small islands of calcified cartilage were present in the bone trabeculae. There was quite a thick layer of cartilage present on part of the articular

surface, rather irregular in width and in the distribution of its cells (fig. 9). Growth, however, seemed almost to have ceased, and though several marrow bays protruded into the cartilage most of them had become lined with a layer of bone. The general appearance was one of inactivity supervening upon excessive growth, and this is in agreement with the man's belief that deformity had not increased for two years.

CASE III.—An officer of 24 complained of prominence of the chin on the right side which made it impossible for him to disguise himself. It was understood that the feature was known to the Gestapo and that he was due to return to enemy-occupied territory in a few weeks. He had first noticed the abnormality two years ago after an aeroplane accident in which, however, he had had no facial fractures. The left condyle occasionally became subluxated. Examination showed the left side of the mandible to be longer than the right, the condylar neck longer and the coronoid process relatively short. I could not determine whether the condyle was enlarged or not. The mid-line of the lower incisors at their crowns was to the right of the mid-line of the upper jaw, and at the apices still more so. The body of the jaw on the long side was less in its vertical measurement than on the short side. There was no clear evidence that the deformity was still progressing but the patient thought it was. Owing to the short time available Sir Harold Gillies decided to reduce the chin prominence by local excision of bone and to change the shape of the nose for good measure. The operations were done from within the mouth and nose respectively, so that no scars were visible.

If this case is correctly diagnosed as one of condylar hyperplasia the deformity is quite likely to recur.

I have re-examined the records of published cases, with the exception of a few recorded in theses and dissertations not directly available here [see table on opposite page]. There are 29 cases including my own.¹

Sex and age.—It appears that Gruca and Meisels were mistaken in supposing that the abnormality is more frequently found in women: 14 men and 12 women were affected in 26 cases. The right and left sides appear to be affected with equal frequency (R. 10; L. 12 in 22 cases). With regard to age distribution it is probable that the date when the abnormality was first noticed was usually several and sometimes many years after abnormal growth had commenced. However, taking the dates available we find that the most common time of discovery was between 15 and 30; and perhaps the abnormal growth usually starts to become significant between the ages of 10 and 25 (age-groups: 0—9, 3; 10—19, 8; 20—29, 9; 30—39, 2; 40—49, 1). Whether it usually ceases spontaneously at some age without operation is not at all clear. In my second case it appeared to be doing so at 36; in Gruca and Meisels' third case the patient at 49 could remember no increase of deformity; and in Heath's second case the deviation was said to have become arrested at 20 after the application of a blister and a course of potassium iodide.

The gross lesion.—In endeavouring to interpret the varied specimens which have been placed on record it is a help to consider what would be the effect of an increased growth-rate just beneath the condylar surface at various ages. In childhood we should expect the result to be a jaw of increased length on the affected side but without much other disproportion of its parts. It can be supposed that the mechanism by which the normal condyle is remodelled to form the neck is usually sufficient to prevent the formation of a much enlarged condyle in childhood, and the effect would be no more than an unduly rapid advancement of the bone in a direction away from the joint. Such a case would be very difficult to recognize as due to condylar abnormality at an early stage, since the upper jaw and other parts would accommodate themselves to the abnormal mandible. My Case III is perhaps a late example of this kind; and the following case may be an earlier example:

Boy 17½ years. He had received a kick on the lower border of the right side of the mandible at 11 years, causing a scar but no fracture. It had now been first noticed that his face was asymmetrical. The right side of the jaw was 1 cm. longer than the left, and it seemed clear that the right side was too long rather than the left too short. The mid-line of the lower incisors was misplaced a little to the left with respect to the uppers and the left canine had erupted outside the arch. The relationship of the first molars was normal on the short side but on the long side the lower molar was anterior to its normal relationship with the upper. Radiographs showed that the body of the long side of the mandible was smaller in its vertical measurement than the other, but little else abnormal. I have postponed decision in this case for one year to discover whether any further deviation will occur.

Another comparable case is that of Perthes (1922) in which the typical deformity had developed from the age of 12 until 16 when it was shown.

¹A further case has now been reported by H. G. Worman, C. W. Waldron, and D. F. Radusch (1946) *J. Oral Surg.* 4, 27; another by J. W. McNichol is in the press.

When the normal growth period of the mandible is drawing to a close an abnormal continuance of growth at the whole condylar surface would lead to the formation of an elongated neck (so long as the remodelling mechanism at the neck persisted) and then to an enlarged head. This result is shown in my Cases I and II and is a more common finding. But it may happen that the abnormal growth-rate continues at only part of the condylar surface, or faster there, with the result that a mass of bone and cartilage arising at that side of the condyle becomes mushroomed over it in such a way as to exclude it from the joint and to replace it as the functional condyle. This is well shown in

TABLE

Author	Sex and age when presented	Age when noticed	Side Deformity	Finding	Other disease
(1) 1836 Adams	F. 30	After 25	R. Much	Ramus asc. enlarged. and supracondylar mass. No cartilage. Autopsy	Rheumatoid arthritis of many joints for 5 years
(2) 1856 Humphry	F. 21	19	R. Much	Condyle enlarged 3 times. Knotty surface of fibrocartilage	None
(3) 1883 Eve (McCarthy)	M. c. 40	—	R. Much	Enlarged body of jaw and supracondylar mass. Autopsy specimen	Arterial disease. Deaf
(4) 1883 Heath (i)	F. 36	26	L. Much	Very large condylar mass, lobulated 1½ in. × 1 in.	Left hemiplegia at 25
(5) 1884 Heath (ii)	F. c. 20	c. 20	— Slight	"Hypertrophy of condylar neck"	None
* (6) 1898 Grube	F. 17	—	— —	Exostosis of articular surface; neck normal	—
(7) 1899 Eckert (Mikulicz)	F. 50	41	R. Much	Supracondylar mass size of small plum. Rest of jaw normal	None
(8) 1906 Eiselsberg (i)	M. 42	39	L. Much	Condyle size of pigeon's egg, lobulated	None
(9) 1906 Eiselsberg (ii)	M. 21	21	L. Much	Condyle enlarged, rough	None
(10) 1907 Riedel	M. Elderly	—	— —	Condyle bigger than a thumb	Deforming arthritis of many joints and trigeminal neuralgia
(11) 1907 Voelker 3 cases	—	—	— Much	Condyle size of walnut, ramus asc. elongated	None

(15) 1922 Perthes	F. 16	12	L. —	Jaw elongated, condyle said not to be enlarged	—
(16) 1926 Gruca and Meisels (i)	M. 24	13	R. Much	Jaw enlarged and supracondylar mass	Rt. otitis media at 10 years
(17) 1926 Gruca and Meisels (ii)	F. 21	15	R. Slight	Condyle and neck enlarged	Rt. otitis media at 11 years
(18) 1926 Gruca and Meisels (iii)	M. 49	Early youth	L. Much	Condyle enlarged, bent back	None
(19) 1926 Wermuth	M. 18	13	R. Much	—	Fell from roof at 12 years
(20) 1927 Ivy (i)	F. 35	32	R. Much	Condyle 3 cm. transverse diam., lobulated	—
(21) 1927 Ivy (ii)	F. 27	26	L. Slight	Condyle uniformly enlarged	—
(22) 1927 Dufourmental (i)	F. 24	18	L. Much	Condyle enlarged, neck elongated; osteophytes	W.R. positive
(23) 1927 Dufourmental (ii)	M. 25	24	L. Much	Condyle enlarged, neck elongated	W.R. positive
(24) 1934 Brodie	M. 19	c. 16	R. Much	Condyle "forward in its fossa"	None
(25) 1944 Rushton (i)	M. 28	27	R. Moderate	Condyle and neck uniformly enlarged	None
(26) 1945 Rushton (ii)	M. 36	16	L. Much	Condyle enlarged and neck very long	None
(27) 1945 Rushton (iii)	M. 24	22	L. Slight	Left jaw and condylar neck elongated	None
(28) 1945 Thoma (i)	M. 37	Childhood	L. Moderate	Condyle very large, jaw not much elongated	Lt. otitis media
(29) 1945 Thoma (ii)	M. —	Childhood	L. Much	Condyle enlarged and ramus elongated	None

*Marked in List of References.

McCarthy's specimen (fig. 10) which Eve interpreted in the same sense, observing further that since the rest of the jaw on the same side was also enlarged the abnormality probably commenced in early life. We do not know when deformity was first noticed in this case, but in a closely similar case published by Gruca and Meisels it was already noticed at 13 years. The original case of Adams appears to have been of the same kind (fig. 11), and the so-called exostosis on the medial side probably represents the remains of the original condyle. The deformity here was supposed to have followed an acute rheumatic

FIG. 9.—Stained Azan. $\times 75$. Fibrocartilage above; then precartilaginous layer, interrupted on right; then hyaline cartilage in which two erosion bays are still active; below, continuous layer of bone (black).

attack at 25, due to living in a damp cabin, but the increased length of the whole posterior part of the jaw on that side and the compensatory downgrowth of the opposing maxilla seen in the lithograph of the skull suggest a commencement some ten years earlier.

It seems likely, however, that in some cases abnormal growth does not begin until the normal growth-period of the jaw has ended. Thus in the famous case of Heath (fig. 12), in which there was enormous overgrowth of the condylar head without remodelling to form an elongated neck, the ramus ascendens and the rest of the jaw were of normal size. And in the well-known case of Mikulicz (fig. 13) described by Eckert (1899), in which deformity was not noticed until the age of 41, it appears (if we can rely on his drawing) that the whole mandible including the condyle was normal except for the extraordinary bony growth from the latter's antero-medial aspect. The fact that here the exostosis did not become mushroomed over the original condyle may mean that it was not in this case formed through a cartilage stage, as indeed the bone at the extreme edges of a normal condyle is not. Eckert says it had an ivory character.

Ætiology.—The association of the deformity with rheumatoid arthritis in the first case (Adams) naturally led to its attribution to that disease, but the subsequent cases already led Heath to doubt this explanation in 1884, and in fact the association appears only once to have been repeated (Riedel, 1907). Arthritic changes noted only in the joint itself (Humphry, 1856; von Eiselberg, 1906; Dufourmentel, 1927) may well have been secondary. An association with hemiplegia in Heath's first case invited the suggestion that neurotrophic effects were responsible, but no support has been provided by other cases. Inheritance and familial distribution have not been known to occur. Intra-uterine malposition (Lohmann, 1919) would be rather unlikely to affect the ramus ascendens, not then formed, more than the parts of the jaw then present or formed in the early years of life; and birth injuries would not cause excessive but restricted growth. Many cases investigated for syphilis have shown no evidence of that disease. Cruca and Meisels' observation of an association with homolateral otitis media in two of their three cases has not been repeated, though it may have occurred in McCarthy's case (*see also* Thoma, 1945). A history of trauma has been uncommon, but blows on the jaw are so universally experienced that no significance can be attached to their mention or otherwise. Eve (1883) considered that the abnormality might well be of the nature of congenital gigantism and pointed to the late development of enlargement in some cases of gigantism of the limbs.

It is certainly true that in cases of unilateral partial gigantism affecting both jaws and the teeth and neighbouring structures there may be enlargement of the condyle and increased height of the ascending ramus on that side (Barwell, 1881; Keith, 1923). However, in all such cases the facial deformity has not been a late development but has been noticed very soon after birth; indeed the fact that the size of the teeth has been affected implies a very early commencement of the deformity.

In the cases discussed in this paper the centre of disturbance appears very localized and probably confined to the condylar cartilage in the first place, though the zygomatic arch sometimes appears thickened.

In several respects the disorder is comparable with the single cartilage-covered exostoses of the long bones. These, according to Geschickter and Copeland (1931), are most commonly discovered between the ages of 10 and 25, which agrees well with the common age of discovery of condylar hyperplasia. Both occur at sites where precartilaginous tissue exists and persists throughout a great part of life; and the structure of both is similar except for a greater tendency to lobulation in the exostoses of the long bones. The factors of trauma and infection which are believed to be instrumental, among other causes, upon the long bones are equally applicable to the jaw. The principal differences appear to be that in the case of the jaw the excess of bone is often remodelled to subserve a functional purpose, that no sex difference is so far apparent in the mandibular cases, and that (so far as I know) malignant change in them has not been recorded. The circumstance that in the temporo-mandibular joint alone does the exostosis occupy the articular surface can be explained on the ground that this joint differs from others in its origin and structure.

Treatment.—Excision of the condyle has long been known to be most successful (*cf.* Humphry, 1856); and the alternative procedure of resecting part of the body of the jaw can only be advisable in cases which are no longer progressive. After condylectomy it is important to see that the patient does not return to the old bite which, as Eckert and others have noticed, has become comfortable for him and even the only position in which mastication is possible; this may entail the extraction of some teeth and the provision of

artificial dentures. Gruca and Meisels wrote: "The earlier the operation is done, the smaller the deformation will develop in the upper jaw and position of the teeth . . . the earliest resection of the articular head is not only advisable, but even absolutely indicated." But there are two difficulties: the first is to be sure at a very early stage that the deformity is progressive; and the second is that condylectomy at such a stage might make that side of the jaw permanently too short. The right course is, probably, to wait until the progressive nature of the deformity is beyond doubt, and until a point has been reached at which condylectomy will leave the two sides approximately equal.

I am indebted to the surgeons mentioned, and to Professor W. Newcomb for sections cut in his department at Park Prewett Hospital, E.M.S. The photomicrographs were made by Mr. T. W. Pearce and Mr. E. B. Brain.

[March 12, 1946]

DISCUSSION ON THE VALUE OF PLAY THERAPY IN CHILD PSYCHIATRY

Dr. Margaret Lowenfeld: To be successful a discussion upon anything must be based upon agreement as to the meaning of the terms to be discussed. It is worth while, therefore, to consider the meaning of the four words in the title.

The word **PLAY** is usually associated with children, but it has a very much richer meaning than that and is commonly used in four senses, all of which go to make up the content of Play Therapy rightly understood.

The word **play** as commonly used in English has four meanings: Play as the opposite of work; Play in association with "games"; Play as it is used in the theatre; and Play in connexion with observation of natural objects, the play of light and shade, for example, and in connexion with instruments, play the piano, the playing of an orchestra.

The essential of the first use is the doing of something for the enjoyment one gets out of it; of the second, the carrying out of a social activity whose essential characteristic is the obedience of all players to prearranged rules. In the third use, the word becomes for the first time serious, and is the presentation of someone not oneself, while the play played by the player presents the author's attitude to men and women, his view of right and wrong and his personal reaction to his personal experience.

The fourth use is curious, it is the use of a mechanical instrument, a piano or a violin to express experiences which cannot be rendered in any other medium, and in which, even if the subject matter be given, the "meaning" given to that subject matter is personal to the player. If we are to use this word correctly as a description of therapy, all four qualities should be included.

To pass to the word **CHILD**, in common speech this word occurs in reference to all ages from about 3 to school-leaving age. The words "infant and toddler" preceding it, and "adolescent" or "young person" succeeding it. On the other hand, when the word occurs in mental hospital statistics, it commonly connotes an age of 16 or 17, and many discussions on matters concerning the children come to grief through lack of preliminary agreement as to the age range which is being discussed.

PSYCHIATRY is a term which originated with adult medicine, and has only comparatively recently come to be applied to children. This is a dangerous process as few concepts, customary and valuable for purposes of description of adult phenomena, can be safely transferred as they stand to children and this is no exception.

The essential of the concept of adult psychiatry is that it is based upon a behaviour criterion. Applied to children this led, quite naturally, to the selection, apart from rare cases of unmistakable psychosis in individuals under 20, of children who failed to conform to the adult conception of correct behaviour, and child psychiatry originated with Healy and Bonner's work on delinquents. Leaving the defectives on one side as falling into a separate class, consideration of delinquent children came to be extended to those unable to show adequate educational progress, to behaviour difficulties within home and school and only in a small part to children with difficulties within themselves. But the scope of modern psychiatry is far wider than this, and includes the psychoneuroses, psychosomatic disorders, and the study of personal anomalies of development. Should not the same range be included in child psychiatry? The value of any form of therapy cannot be assessed adequately until we know to what cases it is proposed to be applied.

With the word **THERAPY** we come to the heart of our problem. What is the goal we are to set before ourselves in child psychiatry? We find ourselves in a curious position. Child psychiatry is in a pre-Krepelin stage of development. Clinical description is the basis of medicine, whether that be psychological medicine or any other. Where are we

to find the clinical descriptions and the systematized psychopathology upon which child psychiatry is to be based? Are we interested in the child himself, and in what study of the child can tell us of the nature of human beings and of the possibilities latent in man? or do we agree with a recent writer that "First and foremost come environment, the parent and the home, then the teacher and the school" . . .? Are we to set as our goal the adjustment of the child to his environment, taking that environment as a given factor, or are we to aim at the development of the potentialities of the individual child? Until we have come to some agreement as to the goal of our work, we cannot estimate the value of any technique that we employ.

Associated with this problem is that of the individual who is to carry out the therapy. If we read carefully Mr. Alexander's Minutes of the Child Guidance Sub-Committee of the Association of Education Committees, we find that "diagnosis and treatment" of the whole range of difficulties occurring in children both at school and at home from the ages of 2 to 18 are to be carried out by "a fully qualified educational psychologist capable both of diagnosis and treatment." When we look further to see what form of training is going to equip such an individual, we find that psychiatry does not appear at all. In Mr. Alexander's view, therefore, the difficulties of children arise in spheres other than those covered by child psychiatry.

Within the field of medicine the views of those who practise child psychiatry range from those of Mrs. Klein and her group of pupils, who demand a very long and highly specialized form of training occupying many years, to those of a recent writer who described her training in the following terms: "Play is the language of children. They know it but we must either recollect it from our childhood memories or acquire it through analysis of ourselves and observation of the child. It is our patient who must help to re-educate us." In certain clinics the practice has grown up that if play is carried out as therapy it should be under the charge of a social worker, but in no case, so far as I have been able to discover, is this accompanied by any suggestion that the social worker should have a training in child psychology, child psychopathology or child psychotherapy.

We now come to the question of play therapy as a technique. There are four types of such therapy. First comes restitutive play. All children need room to run in, a secure atmosphere to play in, earth, air and water to experiment with and enjoy, and things to make and to do. Some children can accommodate themselves to what they get others become ill through the deprivation of these opportunities which modern civilization makes inevitable. Restitution of such elements is a powerful therapy. To make this type of play effective, the right sort of building is necessary, appropriately equipped. With the right people in charge this kind of play can sometimes have a magic effect, but we need to be clear that this is not the magic of psychiatry but of nutrition, the giving back to a starved child essential elements for growth.

The second type is play in groups with the objective of observation of the social behaviour of the children and to give assistance in their social adjustment. The greater the psychotherapeutic experience and understanding of the people in charge, the more likely it is that the group will be able to bring about in the children who take part in it lasting changes in behaviour. But, unless the group is in charge of someone with training and experience in child psychotherapy, this is not a psychiatric method, and non-technical play clubs can show parallel results.

The third type is the play therapy which deals with feeling and phantasy.

Now the feelings and phantasies which underlie neurosis take place within the personality of a patient, and unless he can be induced to tell us about them and has the skill to make himself intelligible, we cannot help him. It is hard enough for adults to convey feelings in words and for children quite impossible. To attempt therefore to do direct psychotherapy with children, whose language is action, without a knowledge of play and without opportunity for the child to express himself in play, is like attempting to treat an adult patient with whom we do not share a common language. It is this difficulty and the lack of adequate understanding of the structure of children's play, and particularly of the fourth form of play therapy, which brings about the confused transference phenomena with children which create so much of the difficulty in this form of treatment. The essential of play, used in this sense, is to put within the reach of children means by which they make clear to themselves and to us their inner experiences of feeling and phantasy: what use is made of the material produced depends upon the theoretical views and technical experience of the adults in charge of the work. The criteria of usefulness is the same in this, as in all forms of clinical medicine; that is, the suitability for treatment of the cases selected, the clarity with which the goal to be achieved is envisaged and the skill of the technician using it.

We now come to the fourth type of play therapy which is my particular contribution, and which I have decided to call direct projection therapy in order to distinguish it from other forms of play therapy, as both its basis and technique are different.

It has been my wish for a long time to achieve something more permanent in the nature of a record of the interior mental and emotional processes of children than the fluidity of play permits. I want to be able to carry away from a play session permanent statements in concrete objects which can be stored for study, much as the preparations in a pathological museum can be stored, so that the personal element can be reduced to a minimum and the records studied scientifically apart from the child, thus enabling progressive comprehension of the phenomena and their objective comparison with each other. I have given fifteen years to this attempt and have succeeded in devising instruments which make this type of permanent objective record possible, and have available over 1,000 cases of children and young adults studied in this way by myself and the group that works with me.

A major aim of this technique is to minimize as far as possible the factor in treatment which is dependent upon the personal equation and the relationship to the adult worker. Each child goes through a regular routine which is clear and definite in the mind of the therapist, but widely flexible in regard to the child. It is also devised to give the child as quickly as possible a feeling of being in a new atmosphere and in a world of his own. For example, the child on arriving for his first visit is greeted by some member of the staff trained in child psychotherapy, and while particulars are being taken from the accompanying adult, is welcomed to a part of the building set aside for children, presented with the mosaic test and asked to make something he likes. It is then explained to the child that what he does in the playroom remains between him and the psychotherapeutic worker and will not be reported upon at home. From then on the child is encouraged to make use of as many of the technical, objective, recording methods as he is inclined to use. There are, for example, hexagon mosaics, kaleidoblocs, design units, on the one hand, and 'world' material, town planning material, &c., on the other, supplemented with verbal methods such as the newspaper game, sentences, &c.

A running commentary is kept up as the child works, making him aware of what he is doing as he does it; but the deeper significance is not interpreted to the child until it emerges unmistakably from his work. In this way what appears is a presentation in which an object, a thought about an object, the same object in quite a different light—perhaps inside out—the essential meaning of the object to the child, and perhaps a puzzle concerning the teacher's name for the object, can all be presented together. Other observers seeing this material are interested in what can be brought about through interpretation of the objects in terms either of their affective meaning or their place in a pre-known theory of the mind. My interest is in the reason why exactly those objects appear at that time and place and arranged in that exact way.

The characteristic of this material is its difference from what one had expected. What is being dealt with in direct projective therapy is not primarily feeling, though feeling comes in later as a consequence of conceptions formed, but the processes of formation of early concepts, of these records of sensation, and the systematization of personal experience which each individual child makes for himself. In U.S.A. Eric Homburger Erickson has been exploring the same region, and Margaret Mead in her recent anthropological study of the people of Bali bases her work on his findings. Schilder's and L'Hermite's work on the body image is relevant to what appears, and much that other workers have done on thought forms in schizophrenia. That is to say that study of a long series of this type of objective production has brought to light a region of human experience as yet uncharted and undescribed. A strange characteristic of it is that there is in it neither time nor space, sequence nor direct causality. What it appears to me we have found in this region is, as it were, the prodromal form, the first or primary form, of thought, and for this reason I have suggested it be called the primary system. As the infant and young child has no frame of reference outside himself, or tool with which his experience can be shared with and checked by the experience of other people, each child has to make his own system of grouping and storing experience, and this becomes the basis of his approach to life. If either his actual experience is usual or his senses no more keen than those of his fellows, then he will sooner or later find words, poems, stories, games, which echo his interior experience, and enable him to pass through it and to make adequate contact with the external world, expressing himself in and through it. If, however, something goes wrong, if he becomes languid, ill, fails to take interest in his school work, fails to want to grow up, odd in behaviour, withdrawn, aggressive, peculiar, then what is happening is that the conclusions he has come to in his interior world are so different from his external experience, so frightening in consequence, that he remains sunk in it and cannot emerge to make contact with outside life.

If, however, working with him we can bring to his aid the facts I have discovered about this part of the mind, with their help discovery can be made of the inter-relatedness on other planes of the objects he presents. The grip upon his mind of these, as

to find the clinical descriptions and the systematized psychopathology upon which child psychiatry is to be based? Are we interested in the child himself, and in what study of the child can tell us of the nature of human beings and of the possibilities latent in man? or do we agree with a recent writer that "First and foremost come environment, the parent and the home, then the teacher and the school" . . .? Are we to set as our goal the adjustment of the child to his environment, taking that environment as a given factor, or are we to aim at the development of the potentialities of the individual child? Until we have come to some agreement as to the goal of our work, we cannot estimate the value of any technique that we employ.

Associated with this problem is that of the individual who is to carry out the therapy. If we read carefully Mr. Alexander's Minutes of the Child Guidance Sub-Committee of the Association of Education Committees, we find that "diagnosis and treatment" of the whole range of difficulties occurring in children both at school and at home from the ages of 2 to 18 are to be carried out by "a fully qualified educational psychologist capable both of diagnosis and treatment." When we look further to see what form of training is going to equip such an individual, we find that psychiatry does not appear at all. In Mr. Alexander's view, therefore, the difficulties of children arise in spheres other than those covered by child psychiatry.

Within the field of medicine the views of those who practise child psychiatry range from those of Mrs. Klein and her group of pupils, who demand a very long and highly specialized form of training occupying many years, to those of a recent writer who described her training in the following terms: "Play is the language of children. They know it but we must either recollect it from our childhood memories or acquire it through analysis of ourselves and observation of the child. It is our patient who must help to re-educate us." In certain clinics the practice has grown up that if play is carried out as therapy it should be under the charge of a social worker, but in no case, so far as I have been able to discover, is this accompanied by any suggestion that the social worker should have a training in child psychology, child psychopathology or child psychotherapy.

We now come to the question of play therapy as a technique. There are four types of such therapy. First comes restitutive play. All children need room to run in, a secure atmosphere to play in, earth, air and water to experiment with and enjoy, and things to make and to do. Some children can accommodate themselves to what they get others become ill through the deprivation of these opportunities which modern civilization makes inevitable. Restitution of such elements is a powerful therapy. To make this type of play effective, the right sort of building is necessary, appropriately equipped. With the right people in charge this kind of play can sometimes have a magic effect, but we need to be clear that this is not the magic of psychiatry but of nutrition, the giving back to a starved child essential elements for growth.

The second type is play in groups with the objective of observation of the social behaviour of the children and to give assistance in their social adjustment. The greater the psychotherapeutic experience and understanding of the people in charge, the more likely it is that the group will be able to bring about in the children who take part in it lasting changes in behaviour. But, unless the group is in charge of someone with training and experience in child psychotherapy, this is not a psychiatric method, and non-technical play clubs can show parallel results.

The third type is the play therapy which deals with feeling and phantasy.

Now the feelings and phantasies which underlie neurosis take place within the personality of a patient, and unless he can be induced to tell us about them and has the skill to make himself intelligible, we cannot help him. It is hard enough for adults to convey feelings in words and for children quite impossible. To attempt therefore to do direct psychotherapy with children, whose language is action, without a knowledge of play and without opportunity for the child to express himself in play, is like attempting to treat an adult patient with whom we do not share a common language. It is this difficulty and the lack of adequate understanding of the structure of children's play, and particularly of the fourth form of play therapy, which brings about the confused transference phenomena with children which create so much of the difficulty in this form of treatment. The essential of play, used in this sense, is to put within the reach of children means by which they make clear to themselves and to us their inner experiences of feeling and phantasy: what use is made of the material produced depends upon the theoretical views and technical experience of the adults in charge of the work. The criteria of usefulness is the same in this, as in all forms of clinical medicine; that is, the suitability for treatment of the cases selected, the clarity with which the goal to be achieved is envisaged and the skill of the technician using it.

We now come to the fourth type of play therapy which is my particular contribution, and which I have decided to call direct projection therapy in order to distinguish it from other forms of play therapy, as both its basis and technique are different.

necessary to have a wide range of material. Sand, water and clay are the three essentials. With these a child will create whatever it wishes. But figures of men, women, children and animals, that permit of the dramatization of the world in miniature, lend themselves admirably to the needs of the child and often simplify the therapist's task of interpretation. Pencils, charcoal, chalks and paints appeal to the majority of children and are most effective where the expanse of paper and the quantities of paints are both large. It is always an advantage if the child feels constrained neither by the atmosphere of the interview nor the limitations of the play materials, but this does not mean an uncontrolled and uninhibited display, whether destructive or not. Such an eventuality could only occur with an unskilled and inexperienced worker.

So far I have only considered play therapy of the individual child. Treatment of more than one child at a time by the therapist has been tried, with varying degrees of success. Unfortunately it has often been regarded as an easy and harmless form of play therapy, open to the less experienced worker, whereas the converse is probably nearer the truth. In my view group therapy, with or without the aids of play material, or dramatic participation, is only effective in a residential establishment, whether hostel or school. The therapist must live with, and therefore be a living part of, the group. To avoid confusion it is probably wiser mainly to restrict the use of the term play therapy to treatment of the individual child.

To recapitulate:

Play therapy is a form of psychotherapy in children utilizing play material as its principal instrument. It is carried out by a therapist having a defined and conscious purpose, namely cure of a disability. The term should be used in no other context.

The technique, and the form of play material, vary with different workers, but fall mainly into one of three types: (a) Passive association and observation; (b) active interference through the play material; (c) verbal interpretation of the play activity.

The play therapist treats the child and should therefore be, or work in connexion with, a child psychiatrist. A lay play therapist forms a valuable, if not essential, addition to the usual Child Guidance team.

Play therapy, like all psychotherapy, is skilled work requiring exceptional personality endowment and prolonged training. The organization of a professional association of play therapists and the formulation and recognition of standards of training are much overdue.

DISCUSSION: PREFRONTAL LEUCOTOMY WITH REFERENCE TO INDICATIONS AND RESULTS

Professor F. L. Golla: The limited time at my disposal can best be filled by considering, in their broadest outlines, the specific effects of the operation of Moniz on the total personality, in the hope that some basis may be formed that will clear the way for a discussion of its therapeutic applications.

The time is not yet ripe when some of the more objective methods can be used to explore these fundamental considerations. "Il est suranné de penser anatomiquement" was the motto that Grasset printed on the title-page of his *Neurology* and though one can hardly expect our friend, Alfred Meyer, to agree with such an extreme functional attitude, I am sure that he would join in deprecating adventures in speculative physiological anatomy not based on experiment. On the other hand, the results of experimental work on the higher apes are not readily applicable to the elucidation of psychological disturbances affecting the least systematized of mental activities. At first sight, one might hope for help from the electro-encephalogram, but the day is not yet when the study of cortical potentials has reached a stage allowing the formulation of a systematic analysis of sub-cortical activities, however confidently we may hope that by some such method an ultimate elucidation of the somatic concomitants of mental activity may be possible.

It is in terms of descriptive psychology that our study must be prosecuted until the time arrives when it may be possible to reinforce psychological inquiry by physiology and the success of our psychological approach will depend on the use of holistic rather than analytic methods.

Let us first clear the ground by dismissing the consideration of the alleged impairment of reasoning as a sequel to the operation. Without going into detail, one may justify this attitude by pointing out that there are a sufficient number of cases in which bilateral

individual, "mad," unrelated, terrifying objects, relaxes, and energy begins to flow through this system to the outside world.

In attempting to describe this region shortly in words, I find myself in a position as difficult as would be that of a pathologist asked to describe actinomycosis without the aid of slides, preparations or drawings. Perhaps the essential aspect is the light this study throws upon psychosomatic conditions in children and upon the genesis of schizophrenia and psychopathic personalities.

In practice all four forms of therapy interweave with each other, and in the Institute of Child Psychology no child or group of children is treated by any one exclusively. It is for this reason that we ourselves feel that a minimum of three years' training, together with a year on the staff and a personal analysis, is necessary for those who would take up the play psychotherapy of children, but we feel that, with this background and correct equipment, play therapy and direct projective therapy form a flexible and delicate technique for the study and treatment of children suffering from the whole range of complaints covered by child psychiatry.

Dr. Alan Maberly: The time would seem opportune for making an attempt to define the nature of play therapy, its place in child psychiatry and the training and status of play therapists. I suggest that the term play therapy should be restricted to a form of individual treatment of children suffering from maladjustment or behaviour disorders involving neurotic disability. It is psychotherapy utilizing play as a principal means of treatment. This is not to say that play may not in other circumstances be constructive and even, in a sense, therapeutic, but it should not be termed play therapy unless the therapist takes an active and essential part.

Play enters into child psychiatric practice in many aspects, apart from its therapeutic purpose proper. For all small children, and some up to adolescence, actions speak more clearly than words, and the therapist must be familiar with every form of symbolism in play whether as a dramatized phantasy or in body language.

We may therefore consider the first function of play as a method of communication. It offers a means of quickly establishing a positive rapport with the child and at the same time opens up a productive path for further investigation. Few children can use words happily to express their feelings, even with adults who are familiar to them, and with strangers self-consciousness and artificiality are inevitable. Play is at once a defence against, and a retreat from, personal contact, which makes free expression possible if not easy.

In so far as establishment of contact with the child is a first essential step in the therapeutic relationship, this first function of play may be regarded as a part of play therapy, but strictly speaking therapy begins when the therapist enters into the play, of set purpose or not. It is important to realize that the child will gradually incorporate an adult into its play, whether or no the latter intends this to be so. Complete passivity on the part of the observer makes no difference—it only makes it easier for the child to attribute to the adult whatever feelings, whether of approval or of blame, he may expect or desire. One might in this way be presumed to approve an action or attitude expressed in the play of which one has no understanding. To this extent a so-called play therapist, untrained and without insight, may achieve a good result by observing the golden rule of a well-intentioned masterly inactivity. But it is not possible to say that such a technique can never do harm, and the ignorant healing the sick is no less inappropriate than the blind leading the blind. The above example, however, illustrates what one may describe as the first of the three principal techniques of play therapy, free play on the part of the child in the presence of a play therapist who remains passive, but in positive relationship with him. Without a positive relationship by which the child senses a friendly and sympathetic understanding, nothing can be achieved at all. Secondly, the therapist can *enter actively* into the play situation, either by a dramatic impersonation, or by interference with the pieces in the game, changing relationships, introducing new figures or removing existing ones. Thirdly, the therapist may *interpret* the meaning of the play to the child so as to bring to consciousness purposes and conflicts that have remained hidden or subconscious. The interpretation may relate to the play as such, or to the child's relationship and behaviour to the therapist.

It is clear that these three methods are in no way mutually exclusive, and all three may be utilized in certain cases either consecutively or simultaneously.

Some therapists lay great stress on the type and variety of play material available, while others attempt a certain uniformity and standardization. I do not think it is possible to generalize, and different workers will develop methods that they themselves find most effective, but to deal with children of all ages and all grades of ability it is

necessary to have a wide range of material. Sand, water and clay are the three essentials. With these a child will create whatever it wishes. But figures of men, women, children and animals, that permit of the dramatization of the world in miniature, lend themselves admirably to the needs of the child and often simplify the therapist's task of interpretation. The interpretation may relate to the play as such, or to the child's relationship and behaviour to the therapist.

It is clear that these three methods are in no way mutually exclusive, and all three may be utilized in certain cases either consecutively or simultaneously.

Some therapists lay great stress on the type and variety of play material available, while others attempt a certain uniformity and standardization. I do not think it is possible to generalize, and different workers will develop methods that they themselves find most effective, but to deal with children of all ages and all grades of ability it is

It is true that restoration may be incomplete and it is certain that it will be carried out by other and more circuitous and clumsy systems of reference. So much may be premised seeing that we are dealing with an interruption of important nerve tracts. I do not know when the process of reintegration ceases any more than I know when we cease to profit from new experiences, but in a case that I have been observing daily for the past eighteen months the process is still going on. And this leads to the last point that I wish to make: Just as the indications for and against leucotomy must be based not on psychiatric classifications of mental disorders but on a study of the emotional subjective self in relation to the total personality, even so must the operation be considered only as a step in the reintegration of personality.

Without due concentration on psychotherapeutic after-treatment, results will often be disappointing.

Friends must be warned that the period of post-operative therapy may be a lengthy one and the physician must be prepared to devote considerable time to the instillation of a sense of responsibility by exploring with the patient such avenues to emotional ethical valuation as may yet be open.

Dr. Walter Freeman and Dr. James W. Watts (from the Department of Neurology, George Washington University. Paper read by Dr. Walter Freeman): *Pain of organic disease relieved by prefrontal lobotomy.*—Among the four hundred patients with mental disorders whom we have treated by prefrontal lobotomy a considerable number have had unbearable pain as the outstanding complaint. We felt justified, when the pain disappeared after lobotomy, in speaking of the relief of mental pain (Freeman and Watts, 1942a). In these cases the complaints of pain appeared excessive and out of proportion to the local condition found on examination. It was equally obvious that we were dealing with individuals who suffered greatly from anxiety, nervous tension, depression of spirit and fear of the future. To them, the sensation was more than pain, it was pain coloured by their gloomy outlook and by the supposed consequences of the pain. Every time the sensation occurred, it meant that something was going to happen or was in process of happening that meant more suffering to come. Sometimes the pain became symbolic of the torment and suffering that the individual recognized as the consequence of previous acts which still aroused feelings of guilt. "This dreadful pain", the agitated old lady would say, "I have only myself to blame for it. I'm on fire. If only my mother had cautioned me against masturbation! I can't go on living this way."

It seems that when the emotional component is reduced, when the feelings of guilt, the regrets for the past and the fears for the future are abolished, the sensations no longer have the same meaning for the patient. We recall an emaciated middle-aged woman (Mrs. C. H.) who had complained of pain in the back of twenty-eight years' duration. Her stomach "went into knots" on the slightest provocation. During the operation under local anaesthesia the patient complained bitterly about her back and her stomach, but paid little attention to what the surgeon was doing. While conversing with her, the neurologist laid his hand lightly upon her scaphoid abdomen and could feel a freely movable mass, probably the pylorus of a greatly ptosed stomach. The patient objected to this, begged him to remove his hand. As the surgeon severed the final quadrant in the frontal lobe the complaints disappeared and with them the palpable mass. In the year that has elapsed since the operation the patient has increased from 79 lb. to more than 100 lb. and has never again complained of either her back or her stomach.

Prefrontal lobotomy relieves anxiety and emotional tension in rather specific fashion. It diminishes concern over consequences. It eliminates the fear of pain. Pain may be present, but when it no longer arouses a mental picture of future disability and all that this may mean in terms of disaster to the person and his family, the experience can be borne with equanimity. Consequently, prefrontal lobotomy lends itself well to the relief of conditions in which the affective component of a painful disorder is equally important with the local condition.

Prefrontal lobotomy has not been used to any considerable extent for the relief of pain in non-psychotic individuals. Usually when medical measures fail to bring relief, the surgeon has severed nerves or spinal roots, resected part of the sympathetic system, or, in extreme cases, has performed anterolateral chordotomy. Sometimes such operations have been gratifying in the extreme, but sometimes, also, they have failed to bring relief. De Gutierrez-Mahoney (1944) has resected the post-central gyrus for the relief of persistent pain, but VanWagenen is the only one to our knowledge who has performed prefrontal lobotomy. The observation is unpublished, but concerns an individual who suffered pain in a phantom limb that defied multiple amputations. The relief was complete.

prefrontal lobectomy or, alternatively, lobotomy has failed to occasion any defect of intelligence while those observations pointing to the contrary conclusion lose their cogency when we remember that the existence of a disordered nervous system has, of necessity, been the circumstance calling for the operation.

A somewhat uncritical application of the Jacksonian concept of "levels" has been invoked as furnishing some support to the view that leucotomy removes the latest acquired inhibitory level. I can only say, without qualification, that I know of no observations that support this interpretation. In Bristol we have endeavoured, with a team captained by Dr. Hutton, to make an intensive study of the effects of the operation on those elements of the total personality that had not undergone demonstrable impairment as a result of the mental disorder. We have obviously had to limit such a study to a small number of selected cases; those in which there is reason to assume that some degree of irreversible deterioration has taken place are, of course, useless.

Let us first consider the immediate effects of leucotomy on the special type of subject that we are investigating. The first and most superficial impression of the post-leucotomy personality is that its possessor exhibits a purely objective mentality.

The subject responds readily and appropriately to variations of the environmental conditions, but seems to take little interest in remoter possibilities.

In no sense, however, can he be said to be deficient in prevision so long as prevision is concerned with the foreseeing of objective and not of subjective changes.

His emotional reactions to appropriate stimuli, directed to cause objective changes in the environment, are to all appearances normal.

Fear, anger and affection may be manifested within normal limits.

In such favourable cases, husbands or wives, friends or business associates, may detect little change from the prepsychotic personality.

At most, the subject may be a little ruder and less sensitive to the feelings of others; sometimes, but by no means often, a trifle more lazy or self-indulgent.

All this is, however, the outward manifestation of a far more radical change.

It is not until one has succeeded in gaining an intimate knowledge of the mentality of these subjects that it becomes apparent that in the early post-leucotomy period we are dealing with personalities exhibiting an impairment of the power of ethical valuation.

Their conduct is, as a rule, irreproachable for, even more than normal people, they are sensitive to the conditioning imposed by their upbringing; they are also acutely aware of the sanctions incurred by transgression of the moral codes. We find them, however, relieved of all sense of personal responsibility and of anxious self-questioning as to the ethical rightness of their conduct.

If one presents to them, for their judgment, problems in behaviour, their verdict will be that of conventional morality but their ethical judgments are determined by purely objective criteria untinged by emotional concomitants.

Man alone of living creatures can feel responsibility for his actions for man alone possesses the power of self-objectification.

This last-developed mental function depends on the integrity of the last-developed structure of the cerebrum, the prefrontal lobe in its relation to the thalamic system of emotional resonance. It is in those disorders of the personality in which we can detect disturbances of this system leading to anxiety states, so often characterized by obsessional conduct, that leucotomy is most successful.

Were this the whole story of leucotomy, grave indeed would be the responsibility of the physician who recommends it, for he must then envisage the substitution of a soulless robot for the insane patient.

Though I am far from denying the gravity of the decision, I think that to put the matter thus is to ignore a very important qualification.

What we tend to forget, or, to put it more offensively, what most of the crude mechanists who teach physiology never let us learn, is the almost infinite lability of the central nervous system. It is not the rigidly departmentalized system analogous to a telephone exchange, dear to the writers of textbooks, but, as the experimental work of Graham Brown and Sherrington, of Lashley and of Weiss, and the clinical observations of Goldstein, have shown, a flexible organic whole which if it cannot arrive at its goal directly will do so by another and less direct path.

Anyone who watches the process of reintegration in a relatively undamaged psychotic personality after leucotomy can trace month by month a return of the power of self-objectification, the sense of personal responsibility, so completely lost immediately after the operation.

It is true that restoration may be incomplete and it is certain that it will be carried out by other and more circuitous and clumsy systems of reference. So much may be premised seeing that we are dealing with an interruption of important nerve tracts. I do not know when the process of reintegration ceases any more than I know when we cease to profit from new experiences, but in a case that I have been observing daily for the past eighteen months the process is still going on. And this leads to the last point that I wish to make: Just as the indications for and against leucotomy must be based not on psychiatric classifications of mental disorders but on a study of the emotional subjective self in relation to the total personality, even so must the operation be considered only as a step in the reintegration of personality.

Without due concentration on psychotherapeutic after-treatment, results will often be disappointing.

Friends must be warned that the period of post-operative therapy may be a lengthy one and the physician must be prepared to devote considerable time to the instillation of a sense of responsibility by exploring with the patient such avenues to emotional ethical valuation as may yet be open.

Dr. Walter Freeman and Dr. James W. Watts (from the Department of Neurology, George Washington University. Paper read by Dr. Walter Freeman): *Pain of organic disease relieved by prefrontal lobotomy.*—Among the four hundred patients with mental disorders whom we have treated by prefrontal lobotomy a considerable number have had unbearable pain as the outstanding complaint. We felt justified, when the pain disappeared after lobotomy, in speaking of the relief of mental pain (Freeman and Watts, 1942a). In these cases the complaints of pain appeared excessive and out of proportion to the local condition found on examination. It was equally obvious that we were dealing with individuals who suffered greatly from anxiety, nervous tension, depression of spirit and fear of the future. To them, the sensation was more than pain, it was pain coloured by their gloomy outlook and by the supposed consequences of the pain. Every time the sensation occurred, it meant that something was going to happen or was in process of happening that meant more suffering to come. Sometimes the pain became symbolic of the torment and suffering that the individual recognized as the consequence of previous acts which still aroused feelings of guilt. "This dreadful pain", the agitated old lady would say, "I have only myself to blame for it. I'm on fire. If only my mother had cautioned me against masturbation! I can't go on living this way."

It seems that when the emotional component is reduced, when the feelings of guilt, the regrets for the past and the fears for the future are abolished, the sensations no longer have the same meaning for the patient. We recall an emaciated middle-aged woman (Mrs. C. H.) who had complained of pain in the back of twenty-eight years' duration. Her stomach "went into knots" on the slightest provocation. During the operation under local anaesthesia the patient complained bitterly about her back and her stomach, but paid little attention to what the surgeon was doing. While conversing with her, the neurologist laid his hand lightly upon her scaphoid abdomen and could feel a freely movable mass, probably the pylorus of a greatly distended stomach. The patient objected to this, begged him to remove his hand. As the surgeon severed the final quadrant in the frontal lobe the complaints disappeared and with them the palpable mass. In the year that has elapsed since the operation the patient has increased from 79 lb. to more than 100 lb. and has never again complained of either her back or her stomach.

Prefrontal lobotomy relieves anxiety and emotional tension in rather specific fashion. It diminishes concern over consequences. It eliminates the fear of pain. Pain may be present, but when it no longer arouses a mental picture of future disability and all that this may mean in terms of disaster to the person and his family, the experience can be borne with equanimity. Consequently, prefrontal lobotomy lends itself well to the relief of conditions in which the affective component of a painful disorder is equally important with the local condition.

Prefrontal lobotomy has not been used to any considerable extent for the relief of pain in non-psychotic individuals. Usually when medical measures fail to bring relief, the surgeon has severed nerves or spinal roots, resected part of the sympathetic system, or, in extreme cases, has performed anterolateral chordotomy. Sometimes such operations have been gratifying in the extreme, but sometimes, also, they have failed to bring relief. De Gutierrez-Mahoney (1944) has resected the post-central gyrus for the relief of persistent pain, but Van Wagenen is the only one to our knowledge who has performed prefrontal lobotomy. The observation is unpublished, but concerns an individual who suffered pain in a phantom limb that defied multiple amputations. The relief was complete.

prefrontal lobectomy or, alternatively, lobotomy has failed to occasion any defect of intelligence while those observations pointing to the contrary conclusion lose their cogency when we remember that the existence of a disordered nervous system has, of necessity, been the circumstance calling for the operation.

A somewhat uncritical application of the Jacksonian concept of "levels" has been invoked as furnishing some support to the view that leucotomy removes the latest acquired inhibitory level. I can only say, without qualification, that I know of no observations that support this interpretation. In Bristol we have endeavoured, with a team captained by Dr. Hutton, to make an intensive study of the effects of the operation on those elements of the total personality that had not undergone demonstrable impairment as a result of the mental disorder. We have obviously had to limit such a study to a small number of selected cases; those in which there is reason to assume that some degree of irreversible deterioration has taken place are, of course, useless.

Let us first consider the immediate effects of leucotomy on the special type of subject that we are investigating. The first and most superficial impression of the post-leucotomy personality is that its possessor exhibits a purely objective mentality.

The subject responds readily and appropriately to variations of the environmental conditions, but seems to take little interest in remoter possibilities.

In no sense, however, can he be said to be deficient in prevision so long as prevision is concerned with the foreseeing of objective and not of subjective changes.

His emotional reactions to appropriate stimuli, directed to cause objective changes in the environment, are to all appearances normal.

Fear, anger and affection may be manifested within normal limits.

In such favourable cases, husbands or wives, friends or business associates, may detect little change from the prepsychotic personality.

At most, the subject may be a little ruder and less sensitive to the feelings of others; sometimes, but by no means often, a trifle more lazy or self-indulgent.

All this is, however, the outward manifestation of a far more radical change.

It is not until one has succeeded in gaining an intimate knowledge of the mentality of these subjects that it becomes apparent that in the early post-leucotomy period we are dealing with personalities exhibiting an impairment of the power of ethical valuation.

Their conduct is, as a rule, irreproachable for, even more than normal people, they are sensitive to the conditioning imposed by their upbringing; they are also acutely aware of the sanctions incurred by transgression of the moral codes. We find them, however, relieved of all sense of personal responsibility and of anxious self-questioning as to the ethical rightness of their conduct.

If one presents to them, for their judgment, problems in behaviour, their verdict will be that of conventional morality but their ethical judgments are determined by purely objective criteria untinged by emotional concomitants.

Man alone of living creatures can feel responsibility for his actions for man alone possesses the power of self-objectification.

This last-developed mental function depends on the integrity of the last-developed structure of the cerebrum, the prefrontal lobe in its relation to the thalamic system of emotional resonance. It is in those disorders of the personality in which we can detect disturbances of this system leading to anxiety states, so often characterized by obsessional conduct, that leucotomy is most successful.

Were this the whole story of leucotomy, grave indeed would be the responsibility of the physician who recommends it, for he must then envisage the substitution of a soulless robot for the insane patient.

Though I am far from denying the gravity of the decision, I think that to put the matter thus is to ignore a very important qualification.

What we tend to forget, or, to put it more offensively, what most of the crude mechanists who teach physiology never let us learn, is the almost infinite lability of the central nervous system. It is not the rigidly departmentalized system analogous to a telephone exchange, dear to the writers of textbooks, but, as the experimental work of Graham Brown and Sherrington, of Lashley and of Weiss, and the clinical observations of Goldstein, have shown, a flexible organic whole which if it cannot arrive at its goal directly will do so by another and less direct path.

Anyone who watches the process of reintegration in a relatively undamaged psychotic personality after leucotomy can trace month by month a return of the power of self-objectification, the sense of personal responsibility, so completely lost immediately after the operation.

This patient did not survive long enough to test adequately our theories concerning the relief of central pain by prefrontal lobotomy; but the immediate result as far as reaction to manipulation of the painful limb was highly suggestive.

CASE IV.—V. S., a white woman, aged 50, complained of intolerable pain and burning upon urination with vesical tenesmus day and night, reducing her to a trembling, weeping invalid. The pains had developed subsequent to operation for prolapsed intervertebral disc during which there was accidental trauma to the roots of the cauda equina. Local procedures, such as re-exploration and removal of more tissue from the disc, resection of the presacral nerve, repeated injections of procaine into the tissues about the neck of the bladder and intraspinal injections of thiamin chloride produced no relief. No local cause for the pain was ever discovered, and neurologic examination disclosed no abnormalities of muscle power, reflexes or sensibility.

After more than a year, during which the only relief obtained was by increasing doses of morphine, prefrontal lobotomy was carried out under local anaesthesia. At first a minimal operation was done, severing only the fibres in the vicinity of the fasciculus cinguli, with the result that the complaints ceased on the operating table. They returned within two days, however, and a week later the operation was revised, severing fibres in all four quadrants in the frontal lobes, with permanent relief of pain. This patient has been followed for nearly two and a half years, and while she has presented many disagreeable personality features, she has made no complaints of pain.

When she was asked about the pain shortly after operation, she replied: "Sure. It's exactly like it was before".

"But you don't complain any more", we suggested.

"What's the use", she answered, "I can't do anything about it so it doesn't do any good to complain".

This patient has gained 55 lb., has needed no narcotics, but when interviewed recently she stated that while she felt no pain, "every drop of urine feels like a barrel". There is moderate urinary frequency about which the patient makes facetious remarks, but her distress vanished at the time of operation and has never recurred.

CASE V.—L. S., a 44-year-old white woman was first seen in November, 1936, at which time she had spent two years in bed because of "arthritis". There was moderate lipping of the vertebrae, but no other significant changes. However, the patient complained so bitterly and was so apprehensive that it was impossible to make any headway in treatment. She had a long history of abdominal operations for adhesions, maybe a dozen in all, was of subnormal intelligence and hysterical temperament. Prefrontal lobotomy was carried out by the Egas Moniz technique November 30, 1936. Within three days the patient permitted manipulation of the limbs. She winced and cried out when the knees were straightened, and the crepitus was very considerable, but instead of shrieking with apprehension and refusing to co-operate she showed interest and willingness to help in the efforts that were made to aid her. On the fourth post-operative day she walked with assistance, and the following day, on attempting to walk unassisted, she fell and sprained her ankle, but nevertheless kept on walking. Her whole reaction to pain seemed to have been altered in that the fear of being hurt no longer upset her emotionally. It has now been nearly ten years since her lobotomy and she has supported herself in adequate fashion in a book-bindingery. When she is asked about her sensations she puts on a long face and tells how terribly she feels, how much her back hurts, how she can hardly walk; and yet she never complains of these sensations to members of the family. (Freeman and Watts, 1942b.)

SUMMARY

Five cases are reported in which prefrontal lobotomy was performed for the relief of pain which had proved refractory to other methods of treatment. In all cases the pains were severe, constant and disabling. In all cases there was considerable structural basis for the pain, yet the emotional component, the emotional response to the pain, seemed to be more disabling than the pain itself.

Previous observations had indicated that when unbearable pain, psychalgia, is one of many symptoms of a mental disorder, prefrontal lobotomy relieves the pain along with the nervous tension and other emotional manifestations. The present cases indicate that when pain due to organic disease becomes unbearable and the fear of pain becomes as dreadful as the pain itself, prefrontal lobotomy is a desirable procedure.

Psychosurgery alters the individual's reaction to pain without materially changing his ability to feel pain. Pain may be present, but when divorced from its implications— insecurity, disability, guilt, death—it then becomes bearable and may be accepted with fortitude.

The speaker demonstrated the principles and surgical technique of prefrontal lobotomy by means of a sound film in technicolour prepared by The Psychological Cinema Register, Pennsylvania State University, Pa. This film dealt with the marks on the skull, the tracts severed at operation and the various surgical details of the procedure of prefrontal lobotomy of the so-called standard type in the plane of the coronal suture.

We are reporting our experiences with prefrontal lobotomy in the relief of pain from recurrent carcinoma, tabes dorsalis, thalamic syndrome, trauma to the cauda equina, and hysterical contractures.

REPORT OF CASES

CASE I.—T. P., a 45-year-old white man, developed carcinoma of the rectum in 1942 which recurred in 1944 with severe pain in the perineum and down both legs. Anterolateral chordotomy was performed on both sides, with the production of analgesia on the right side but not on the left. In spite of this, the patient continued to suffer severe pain on both sides. Metastases occurred to the liver and lungs, with a great deal of abdominal pain which could be controlled only partially by morphine every three hours. The patient was in precarious condition, suffering constantly, unable to eat or sleep with comfort. His anticipation of pain was also pronounced. Even as he was being given a hypodermic he would say: "When the effect of this morphine wears off, you won't let me suffer, will you, Doctor? You'll give me another hypo, won't you?" He begged the nurses to give him something for his misery, saying that he was going to die anyway and might at least be given comfort. The emotional reaction to pain in this case seemed to be of such great significance that prefrontal lobotomy was proposed to him and he accepted it with relief, "anything you can do to ease this pain will be a blessing".

Prefrontal lobotomy was carried out April 27, 1944. Following operation the patient was dull and confused for a brief period but acknowledged his comfort, and no longer demanded morphine. In fact very little sedation was required and for a period he gained somewhat in ability to eat and sleep. With the progress of the disease the liver became more and more enlarged until it practically filled the abdomen. As long as the patient was not disturbed he voiced no complaints, but if he were moved, or the hand was placed on the abdomen he grimaced with pain. The analgesia to pin-prick was exactly as it had been before the lobotomy. Even his reaction to the inevitability of death seemed to be altered. Asked if he knew he was going to die, he replied: "Sure, everybody has to die, don't they?" This fortitude in the presence of pain and impending death continued until his demise August 1, 1944.

CASE II.—W. P., a 50-year-old white man, had been under treatment for tabes dorsalis since 1934. He had undergone malaria treatment and prolonged chemotherapy thereafter, so that the spinal fluid had become entirely normal. Nevertheless the pains persisted. The patient was of a rather worrisome type, thin, restless and anxious. He made a good income from driving a taxicab, but had to spend as much as \$60 to \$80 a week for morphine injections which gave him the only relief he could secure. As long as he remained completely quiet at home the pains did not bother him, but any activity seemed to excite them. Here again, anticipation of pain seemed to be the disabling factor in his condition. "I guess I could stand the pains if it weren't for the thought of them coming on". Domestic difficulties were also a source of distress to him, and prevented earlier carrying out of the proposed operation. Meanwhile one of his comrades in suffering, also a tabetic, committed suicide. The patient's family finally consented. Prefrontal lobotomy was carried out on December 4, 1944. Narcotics were discontinued. He continued to have attacks but he described them as twinges and he never complained about them. Because of the domestic situation and his lack of ability to care for himself adequately he was admitted to St. Elizabeth's Hospital and there is making himself useful to other patients in the ward. In the year that has passed since operation he has gained considerable weight, but the signs of tabes are as obvious as ever. His perception of pain is as keen as before, but his reaction to pain lacks the emotional component that was disabling. His euphoria is decreasing and his sense of responsibility growing so that he is allowed out of the hospital on extended visits.

CASE III.—L. McL., a 55-year-old white woman, red-headed with a corresponding disposition, suffered in childhood from rheumatic fever with resulting mitral stenosis. Embolism of the right renal artery occurred in 1932, with recovery after nephrectomy. In October 1939 she suffered cerebral embolism with resulting paralysis of the left side. Recovery was gradual, but beginning six weeks after the stroke she suffered disagreeable pains centring about the left side of the neck and running down into the fingers. The pains were aroused by any muscular activity, and particularly by emotional outbursts which were fairly frequent. They quieted down during relaxation and did not interfere with sleep. Examination showed weakness and spasticity of the affected limbs, with hyperextensibility of the fingers. Pinching, scratching and chilling with ice were unendurable. There was marked loss of the sense of position in the fingers. Since the arm could not be manipulated without provoking the hyperpathia and arousing emotion verging on rage, this patient had to live in very secluded fashion. After more than two years' ineffectual treatment prefrontal lobotomy was carried out on June 16, 1943. For the first two days she was drowsy and unresponsive; then she developed abdominal rigidity and distension and winced and cried out when the lower abdomen was palpated. She permitted manipulation of the left arm, and reacted only mildly to scratching and the application of cold. Death occurred on the fourth post-operative day from peritonitis due to a ruptured diverticulum of the sigmoid.

Examination of the brain showed the surgical lesions opposite the genu of the corpus callosum filled with clotted blood and friable material. The old infarct destroyed the bulk of the putamen and caudate nucleus, sparing the insula, thalamus and globus pallidus. In the thalamus, however, the centrum medianum on the right side was completely atrophic, the nucleus ventralis anterior and anterolateral parts of the nucleus medialis dorsalis showed moderate degeneration; and the dorsolateral part of the nucleus ventralis lateralis was partly degenerated. The right pes pedunculi was quite small and markedly degenerated in its medial portion.

this group were vertical incisions above the orbital cortex, the difference being that one was made half a centimetre deeper into the brain substance than the other. 35% of the 26 made good improvements, 5 of the 9 cases with good results were schizophrenics with some depressive features and two others were melancholics. According to our investigations this vertical incision is the lowest that can be made without significant hæmorrhage if a leucotome is used.

TABLE II.

	Good	Fair	Poor	Died	Total
Upper	15%	42%	41%	2%	52
Middle	11%	32%	53%	4%	71
Horizontal... ..	20%	33%	44%	3%	30
Lower	35%	42%	23%	0%	26
	17%	37%	43%	3%	179

One of the two incisions not included in the series was a lower vertical and horizontal combined, the other a cut parallel to the orbital cortex in a plane 15 to 20 degrees below the horizontal. Our experience of these is small as yet.

From an analysis of the results so far obtained it appears that the symptom of depression is best relieved by a lower incision, that the aggression of the catatonic may improve from a high incision and the paranoid schizophrenics may derive most benefit from the middle vertical combined with a horizontal incision. As yet it is too early to speak with any real assurance about these findings as the numbers are small for comparison and we have been tending to make lower and lower incisions in better and better patients.

The clinical differences produced by the middle and orbital incisions are very noticeable, although there is only about $\frac{1}{4}$ cm. difference in level between the lowest points of the two circular cuts. With the lower there is more headache, drowsiness, a disinclination to eat, restlessness, transitory neurological signs such as incontinence, irritability and upgoing toes, usually a more rapid pulse-rate and for the first four or five post-operative days there is considerable difficulty in assessing how much improvement the patient may eventually make.

By way of complications we have had 5 deaths. 4 from hæmorrhage and 1 from pneumonia, all occurring in the first 83 patients. With a gas, oxygen and ether anæsthetic there have been no deaths in the last 103 cases.

Three patients have had a single fit, a fourth two. One patient has been incontinent of urine since her operation but she is aware of it. One patient developed marked apathy for six weeks after operation and is clearing up slowly.

In conclusion I think we may first say that by using a minimal incision to avoid deterioration, very satisfactory results may be obtained from chosen patients even if they have failed to react to the other forms of treatment. Secondly, the effects of the lower incision appear to be better than the remainder particularly if there is a depressive element in the illness.

We wish to thank Dr. F. Reitman for his help and suggestions; he has been associated with us in the latter part of the work.

Dr. L. C. Cook: Among those with practical experience of leucotomy there is no doubt as to the important place it must take in our present armamentarium of treatments. Nevertheless, some recent criticisms, although manifestly ill-informed and actuated by deeply rooted unconscious antagonisms, may be useful in curbing the enthusiasms of the more impetuous exponents of physical methods in psychiatry. The risks of leucotomy are such that it should never be regarded as a routine method for any condition, and personally I should not care to take the responsibility of advising the operation for any patient I had not had under close observation, preferably as an in-patient, for a considerable time.

Experience has taught us that leucotomy is of greatest value in relieving states of morbid emotional tension and distress, and disrupting the behaviour patterns dependent on them, and that it is not a specific remedy for any particular mental disorder.

For convenience of classification likely candidates for this treatment may be placed in four groups:

- (1) Depressive psychoses with severe agitation and apprehension, in which convulsion treatment has failed or is contra-indicated.
- (2) Obsessive-compulsive states, where anxiety and rumination are of a grave degree of severity.
- (3) Some florid schizophrenic reactions with distressing hallucinations and delusions, and heightened affect.
- (4) Long-standing violent conduct disturbances associated with increased mental tension, occurring mainly in catatonic and paranoid-hallucinatory schizophrenia, but also in some aggressive psychopaths, encephalitics, epileptics and mental defectives.

Dr. E. Cunningham Dax and Mr. E. J. Radley-Smith: We mentioned our first two cases of section of the lower part of the frontal lobes in 1943 but a more detailed description is found in Hoffstatter, Smolek and Bush's article (1945, *Arch. Neurol. Psychiat.*). It will be seen that in this present paper the positions of the brain sections methodically work down to the orbital cortex.

Briefly there is evidence that the orbital cortex, perhaps together with a portion of the temporal lobes, forms a functional unit which may be called the emotional cortex. Work by Legros Clark, Earl Walker and Meyer has shown the extent of the anatomical representation of the orbital cortex in the thalamus, and its clinical importance has been emphasized by Spatz, Rylander and others.

There are two particular points we would like to make which may be of interest. First that the approach to our last 130 cases has been made through the temporal fossa thereby giving a landmark for a constant plane of section. Secondly that we have always used a Macgregor-Crombie leucotome, with the definite intention of dividing a comparatively small number of fibres, hoping thereby to avoid the signs of deterioration described after the use of the more extensive operation.

The temporal approach is made from a point 3 instead of the usual 6 cm. above the zygoma, thereby allowing the Sylvian vessels to be seen as a landmark in every case. From this point different sections can be made both vertically and horizontally by varying the depth of incision and the direction in which the leucotome is pointed.

We have made bilateral incisions in this way in nine different positions, in the main on disturbed patients of long history.

The position of the sections has been worked out on fresh post-mortem material prior to operation. This was done by marking the brain through the drilled skull with coloured dyes according to the points at which the leucotome should be directed, sectioning the removed brain through the dye marks and making tracings against which the leucotome could be laid and the sections drawn.

In general our cases have been divided into two groups. In the first, 125 operations were performed for gross conduct disorders the majority being patients with long-standing psychoses. The second group of 54 were considered to have a possible chance of recovery by operation judging them as a whole, even though in all but four paranoid schizophrenics each had been treated by the usual methods such as insulin comas, convulsion therapy and prolonged narcosis.

Classifying the results into good, fair and poor, 9% of the 125 in the first group were good, 42% were fair and 46% were poor. Of the 54 in the second group, however, 37% were good, 37% fair and 22% poor.

TABLE I.

	Good	Fair	Poor	Died	Total cases
Group 1: Conduct ...	9%	42%	46%	3%	125
Group 2: Personality ...	37%	37%	22%	4%	54

An analysis of the cases according to the type of incision used is perhaps of greater interest from the point of view of this paper. In order to simplify the results and give adequate numbers for comparison the cases are divided into four groups representing seven types of bilateral incisions.

The first comprises those with an upper incision 6 cm. above the zygoma—the planes of section in these cases are probably variable. There were 15% good results in 52 cases. The catatonics did fairly well with this incision, 3 out of 9 making a good improvement.

The second group comprises those operated on by what we might call a middle incision. The leucotome was entered at a point 3 cm. above the zygoma and pointed at the junction of the middle and upper thirds of a line joining the zygoma to the vertex in the plane of the coronal suture on the opposite side of the skull. 11% of the 71 cases made a good improvement. 4 of the 8 good results in this group were paranoid schizophrenics.

The third section comprises three different incisions. The first was a bilateral horizontal cut by pointing the leucotome, from the temporal approach, at a point 1 cm. above the supra-orbital notch of the opposite side. The second incision was also horizontal but more posterior, the third combined the horizontal and middle vertical incisions. 20% of 30 cases in this series made a good improvement. 3 of the 6 good results were in paranoid schizophrenics but in each the vertical incision was also made. The other 2 making good improvements were agitated depressives with paranoid features who had not responded to full courses of convulsion therapy.

In the fourth group the material was better, being largely young schizophrenics who had failed to react to insulin and convulsion therapy. The two operations included in

Tables of leucotomy results are of such little value unless correlated with their previous prognosis that I would make a plea that whenever detailed tabular results are given a prognostic column should be included.

RELAPSES

Among these 48 cases there have been only 4 relapses. The 2 cases of agitated depression relapsed after approximately eighteen months, and 2 subjects of somatopsychic delusions after four to five months. The latter discharged themselves rather too early, and although one of them was free from symptoms at the time, neither had recovered. Variations both for better and worse often occur up to nine months or so after operation, but striking changes are uncommon after a year, and I think it is fair to say that patients who have kept really well for eighteen months may look upon themselves as permanently recovered.

A noteworthy feature of this series is the rarity of frontal lobe injury symptoms—notably emotional flattening, lack of initiative, indolence, irresponsibility, facetiousness and lack of modesty. These and other undesirable sequelæ have been an alarming feature of Freeman and Watts' series and must have great weight when considering leucotomy. Of the 26 patients in my series discharged from hospital or greatly improved only 1 showed any facetiousness and irresponsibility and only 3 any significant slowness and lack of initiative—and all 4 of these are earning their livings or looking after their homes. All my patients were operated on by Mr. Wylie McKissock and I wonder whether their relative freedom from frontal lobe symptoms may be due to some slight difference in his technique although I understand his methods are very similar to those of Watts. It is noteworthy that 3 of the 4 cases mentioned were operated on at the same session, although Mr. McKissock assures me that he did not consciously alter his technique on that occasion.

Lastly, it is of the utmost importance to discover in patients who have made good recoveries what brain changes are to be found. Dr. Alfred Meyer has demonstrated among other things varying degrees of degeneration of the dorsomedial nucleus of the thalamus, but none of his cases can be said to have fully recovered. It is not easy to obtain the brains of patients dying, perhaps years later, in the ordinary way of things. All we can do, and I think we ought to do, is to urge the nearest relatives of our patients to let us know if ever they are admitted to hospital, so that we can effect a liaison with their doctors.

Dr. R. Ström-Olsen: In Table I I have set out a summary of the results in 106 cases out of a total of 116 operated on at Runwell Hospital by Mr. Geoffrey Knight. From these results it will be seen that roughly two-thirds have benefited to a greater or lesser extent from the operation, whilst of the cases "not improved" 2 have actually been made worse mentally.

Indications for treatment are, of course, arrived at by a careful study and follow-up of cases treated. From this it would appear that the most favourable outcome can be expected in obsessional neurosis, chronic melancholia, whether involutional or otherwise, and in paraphrenia and chronic paranoid states showing psychomotor unrest and anti-social behaviour due to delusions and hallucinations. In the obsessional states successfully treated, all the patients completely lost their obsessive thoughts and compulsions and the results were really dramatic. In the other conditions mentioned the complete relief of emotional distress was also very apparent in the favourable cases. In other psychotic

states, schizophrenia, epilepsy, chronic mania, psychopathic states, the effect was not quite so favourable although there were a number of social recoveries. The most important effect was that patients with a disturbing influence became quieter and more manageable, thus obviating the need for the same close nursing supervision as formerly, and the output and quality of these patients' work undoubtedly improved. There was no apparent effect on the incidence of fits in epileptics. The common factor in these conditions would appear to be the overwhelming effect of a severe and prolonged disordered emotion, and certain psychotic symptoms such as hallucinations and delusions, on the patient's

RESULTS

In giving the results of 48 patients treated at Bexley Hospital I am including only those operated on more than nine months ago, because the changes after leucotomy often continue for many months, and I do not think any reliable estimate of result can be made for at least nine months if not a year.

TABLE.

Diagnosis	Recovered or remitted	Greatly improved	Conduct improvement	No improvement	Died	Out of hospital	Known to be working	Relapsed	Total
Agitated depression	8	—	—	1	1	7	4	2	10
Schizophrenic reactions	2	1	1	1	—	3	3	—	5
Schizophrenia	5	4	7	5	1	8	7	—	22
Aggressive psychopaths, &c.	1	1	2	—	—	1	1	—	4
Other conditions	3	2	—	1	1	5	3	2	7
Total	19	8	10	8	3	24	18	4	48

By recovery I mean that the patient appears to be quite normal in conversation and conduct both to the physician and to relatives living with him; by remission, loss of all symptoms of the disorder for which he was treated. I have not attempted to separate these groups because the standard of normality is too equivocal. Several of those classed only as greatly improved are out of hospital doing full-time work or keeping house successfully.

Of the 10 agitated depressives, 7 had previously had E.C.T. with only temporary benefit; in the remaining 3 it was contra-indicated for physical reasons. 8 remitted and 6 remain quite free from symptoms; 2 relapsed to some extent. 1 died six days after operation and 1 shows no improvement.

Of those I have classified as schizophrenic reactions (admittedly a quite artificial group) the prognosis would have been promising had they not sounded a warning note by failing to respond to other treatments. Duration of symptoms averaged just under two years, but their extreme tension and distress associated with vivid hallucinations gave us little option but to operate. 2 have shown complete recovery for over two years and 1 other has been working for nearly three years.

In the schizophrenic group the prognosis was uniformly bad, and in a number of cases frankly hopeless and only conduct improvement to be expected. Nevertheless 3 of this group appear to have made complete recoveries and have stayed well during a period of three to four years, while 4 others are carrying on successfully at their jobs. One other has recently left hospital and I think will soon be earning her living. Only 5 have shown no improvement.

The prognosis in all 4 aggressive psychopaths was considered quite hopeless, yet one girl who had literally smashed up the hospital for nine years after her transfer from a mental deficiency colony in 1933 has become stable enough to earn her living in domestic work for eighteen months. One encephalitic has lost all her former all-too-frequent urges to smash and 2 others, a troublesome encephalitic and an aggressive epileptic, show some conduct improvement.

Other conditions include 3 subjects of long-standing somatopsychic delusions, one case of chronic mania, who remains materially unchanged, 2 mixed cases and 1 case of severe coprolalia and head striking (La Torette's syndrome). This lady whose symptoms dated back some eight or nine years and who had maintained for several years a completely bent-double position and was unable to complete a sentence without a half-dozen interpolations of the same obscene word, slowly but surely improved and is now at home living a normal life and is quite free from her habit-spasms. The somatopsychic delusional cases comprise a group difficult to classify, merging on the one hand with hypochondriacal depressives and on the other with paraphrenics, while all show a strongly obsessional attitude. The results were disappointing; one patient lost all his symptoms but failed to gain real insight and relapsed in four to five months, and another improved greatly but likewise relapsed; the third is in no way troubled by her delusions eight months after her leucotomy but they still remain in the background.

Dr. Freeman's remarks on the relief of pain through leucotomy are to some extent borne out in the case of a patient operated upon too recently for inclusion in my list. He described among other somatopsychic complaints, agonizing pain in the jaws and mouth. Since his leucotomy nearly three months ago he says this pain scarcely troubles him. He is, however, a chronic bronchitic subject to acute exacerbations and his somatopsychic complaints tend to wax and wane with his physical symptoms. It will be interesting to see whether his relative freedom from pain survives an acute attack of bronchitis.

It will be seen that out of 48 patients 24 are out of hospital and 18 known to be working full-time or looking after their homes. Considering the prognosis in these cases the results must be considered most encouraging, and in some of the schizophrenics they have been truly dramatic. I attribute the unusually good results in relation to prognosis to the fact that only patients showing marked tension were chosen and that leucotomy has not been performed as a routine on a mass of chronic hopeless psychotics.

often not noticeable during the patient's stay in hospital. An analysis of these undesirable symptoms is shown in Table III. It does not purport to be by any means a complete

scientific analysis of the psychiatric complications and sequelæ. It is; however, a useful guide or statement of observations made by relatives, and shows the incidence of the various symptoms or complaints as observed by them, and/or the psychiatric social worker and psychiatrist. The true picture of the personality change can only be demonstrated by a detailed clinical history in each case. It is quite obvious, however, that there are many disquieting features in the changes observed.

Whilst there is no doubt that the balance of opinion is much in favour of the operation, one has to bear in mind the possibility of the development of these quite serious personality disorders before recommending any patient to undergo the operation. The following remarks made by relatives are illuminating: "She often embarrasses us but it is lovely to think she is so well", and "For her this operation has been a miracle, but we wish we had not got to live with her".

The *sine qua non* of indications are therefore (1) incurability by other means, (2) the severity and disabling effect of symptoms, and (3) chronicity.

One may speak with greater certainty and favour of the effect of leucotomy on selected patients of the chronic psychotic population of a mental hospital, i.e. paraphrenics, epileptics, schizophrenics, who are not likely to be discharged. In the majority of them, although leucotomy is only a palliative measure it has resulted in a marked improvement in the severe disturbance of behaviour seen in this type of case, and this improvement has been of great practical importance. Patients are quieter, more manageable, they feel more comfortable and require less nursing supervision than formerly, and their output and quality of work have improved.

Major J. N. P. Moore, R.A.M.C.: *Prefrontal leucotomy—Report on 150 cases at the Crichton Royal Hospital.*—When we considered using the operation more than three years ago we did so in a sceptical frame of mind, critical of the empirical nature of the procedure. For, while there is no doubt that the brain is the organ from which the symptoms originate, it is by no means certain that it is the seat of the disease process as a whole. Thus we chose cases, which, judged by ordinary prognostic standards, were hopeless, chronic invalids. Of the first 100 cases, a report on which was published six months ago, the average duration of the present attack was eight years and only 5 had been ill for less than two years. In most of them the better established forms of treatment such as electric convulsion therapy and insulin therapy had failed to produce more than transient improvement. The criterion for selection of cases was the presence in the clinical picture of signs of mental tension, shown by such symptoms as irritability, rage, fear or other forms of emotional excitation, insomnia, and on the motor side, restlessness, aggressiveness, destructiveness or impulsive behaviour.

Now the series has increased to 75 male and 75 female patients whose average age was 35 years, ranging from 18 to 65 years. It includes 8 cases of melancholia showing marked signs of tension for many years, a case of recurrent mania of ten years' standing, and 7 severe obsessional states. It also includes 4 organic cases; these are a general paretic who after fever treatment developed a chronic hallucinosis, a Parkinsonism with a super-added agitated depression, and 2 epileptics subject to fréquent equivalents with impulsive outbursts. The remaining 130 cases were suffering from schizophrenia—mainly aggressive, restless, negativistic paranoids and catatonics. Only 22 were hebephrenics. 8 of the catatonics showed a well-marked periodicity of their symptoms.

RESULTS

As pointed out in a previous communication, in chronic cases such as these it is not possible to adopt the rigid criteria of recovery that one would apply to more recent cases, and the grading of patients is thus to a certain extent relative to their pre-operative state. In order to make the meaning of the table quite clear I should like to define the standards

conduct, resulting in severe disability, anti-social behaviour, extreme restlessness, violence, destructiveness and suicidal tendencies. I purposely use the adjectives "severe" and "prolonged" because the present-day operation, even in the hands of the most expert surgeon, is fraught with dangers and risks which one cannot afford to overlook. I would therefore stress that cases should only be considered for leucotomy who have had a thorough trial of all other forms of treatment and whose illness has lasted sufficiently long to leave no reasonable doubt that a remission or recovery cannot take place by any other means, or where the disability is so extreme as to make the risk worth while. In our own series the duration of the illness in by far the majority of cases was more than five years. In only 9 was the duration under five years, and of these only 2 were between two and three years' duration.

In the 116 cases operated on the immediate post-operative deaths numbered 4, or 3.4%. All were due to cerebral hæmorrhage. Other deaths attributed to the leucotomy, occurring four and five months respectively after the operation, numbered 2. The cause in one case was toxæmia and exhaustion due to nutritional and trophic disturbances, and in the other, cerebral softening due to old hæmorrhage. Further, in 95 non-epileptic patients operated on, 6 developed epileptiform seizures, 3 of whom have been quite severely affected. I am not qualified to talk of the surgical aspect, but I would like to mention in passing that recent pathological evidence seems to show that hæmorrhage may be due to section of thin-walled veins, sometimes aberrant or anomalous in pattern, whose resistance cannot probably be felt even by the finest of instruments. This is obviously a grave drawback to the method of blind approach.

We are further hampered in framing criteria for indications by the fact that recent histological and other evidence tends to show that there is a very limited zone in the prefrontal white matter in which surgical section is effective in severing the all-important fibres, and that landmarks on the skull and surface of the brain would appear to be uncertain guides to this circumscribed zone.

Table II shows the analysis and follow-up of 31 cases discharged. Regarding the condition on discharge, 18 were observed in hospital for more than six months, 5 for three to six months and only 8 from one to three months. The duration since leucotomy in these

cases varies from three months to four and a quarter years, the average duration being two and a quarter years. It will be seen, therefore, that out of a total of 31 cases discharged, nearly half, viz. 48.3%, have shown an entirely satisfactory result so far. In view of the very chronic and intractable nature of the cases treated, this number, although comparatively small compared with the whole series, must be considered highly gratifying. As the time which has elapsed since leucotomy is reasonably long there is every likelihood of these results being permanent, but of course the follow-up on all cases will continue and the condition will be reassessed from time to time. One significant observation is that while some patients can be regarded as recoveries or much improved whilst hospitalized and living under sheltered conditions, when they are discharged and have to adjust to outside life some break down and react unfavourably. From an intensive follow-up study in which both relatives and patients have been interviewed, either by our senior psychiatric social worker or by myself, it was apparent that the interaction of the patient with the outside environment brought out undesirable symptoms which were

our cases was the illness of shorter duration than three and a half years. 2 of our group of 8 melancholics recovered, 3 are much improved. Our one case of recurrent mania has had her operation too recently to judge the ultimate outcome but she has been consistently well during the ten weeks which have elapsed since her operation. Our experience with organic illnesses is too small to draw any conclusions but one of the two epileptics has improved in that her violent psychomotor equivalents are less severe, and the distressing agitation in the case of Parkinsonism has been relieved completely.

I may sum up by saying that the outstanding impressions gained from more than three years' experience of the operation are the excellent results in obsessional states, the encouraging results in chronic melancholia and above all, the remarkable change in outlook for the distressful cases of schizophrenia which form such a large proportion of the chronic population of our mental hospitals. The most urgent problem in regard to the operation appears to be the need for a systematic study of recovered cases, especially those who have had the treatment at an early stage of their illness in order to assess more accurately the degree of personality change which follows the lesion to the frontal lobes.

Dr. Jan Frank: *A review of 200 cases of leucotomy at Graylingwell Hospital, Chichester.*—The length of observation varies from eight months to three years. Social recoveries were regarded as those who are capable of independent management of their own affairs, occupy a post, have the type of work they had formerly, and are, at the same time, able to appreciate the enjoyments of life. Insight regarding their previous illness is not included in the definition of social recovery.

In the improved category are patients who attained a better social adaptability, are easier to manage, and have much fewer psychotic symptoms. They are not well enough to live on their own and are not self-supporting. More than half of the improved cases are for long spells, or permanently, in the care of their family. They are usefully occupied, though at times with stereotyped tasks. The average duration of hospitalization prior to the operation was four years, three months, ranging from a few months up to fourteen years. 35% of the total had spontaneous remissions lasting from three to eight months, but none got well enough to interrupt social invalidity, which in all was continuous and of at least three years' duration.

The indication for leucotomy in these 200 cases has been put forward as a last resort only. Other forms of treatment, including systematic psychotherapy when practicable, also outside the hospital, have been tried but failed. In the first 75 cases, distressing symptoms determined the choice of leucotomy. With more experience, our guiding criteria, apart from hopeless prognosis, were as follows:

A prepsychotic personality with good or fair record of social adjustment. In the clinical picture, a plasticity of symptoms such as delusional productivity, and some vestiges of resistance to total psychotic surrender should be present. Paramount of all is, however, a conflict situation with emotional colouring.

We found, from the psychiatric aspect, leucotomy contra-indicated in patients with *a priori* shallow affect, as revealed in the study of their prepsychotic personality. For schizophrenics in whom there is an established formal thought and language disorder (Kasanin, Goldstein), coupled with other primary symptoms, such as dissociation of conation, psychic anergy, the usefulness of leucotomy is problematical if the manifest psychosis is of longer than three years' duration. Nuclear schizophrenics of the chronic catatonic or paranoid group, if they do not respond to insulin, should have leucotomy as early as possible, before cognition is hopelessly disturbed.

Our observations and results bear out that in patients whose psychic drive is either constitutionally low, or slowly petering out, due to the schizophrenic process, a more anteriorly placed cut than that stipulated by Freeman and Watts should be performed. Mr. Ross, who operated on all the reported cases, takes his measurements on the skull 2½ cm. anterior to Freeman and Watts—when required to do so. With this modification we certainly achieved less spontaneity, loss of initiative and emotional bleaching, than in the first 75 cases which were all operated on according to Freeman and Watts' instructions.

Cerebral arteriosclerosis, organic senile syndrome, should be carefully excluded from the involutional group, as leucotomy precipitates their deterioration. If the clinical signs are ambiguous, the state of the retinal vessels, an "organic" Rorschach, and discrepancy of verbal to the disadvantage of performance intelligence test scores are of great value to us; also the positive correlation of high blood urea and organic mental condition, established by Richter. We found a blood urea of over 50 mg.% an absolute contra-indication for the operation. 16 patients in this series were over 55 years of age.

In paraphrenics, although the results are very encouraging, leucotomy is justified only when spontaneous improvement is excluded; in manic-depressives, although the classical Freeman and Watts posterior cut seems to be able to arrest the psychotic mood-swings, only too-quickly alternating episodes warrant leucotomy. The numbers are not sufficient to state with statistical validity whether leucotomy is definitely capable of stopping cyclothymic swings; the clinical impression, however, suggests that it does.

In assessing complications and results, it has been found impossible to state anything

we have adopted. The term "recovered" must be taken to mean social recovery, i.e. ability to leave hospital, live at home under normal conditions and resume some form of useful employment not necessarily up to former standard.

RESULTS IN 150 CASES.

	1943	1944	1945	1946	Total

Dead	4	—	—	—	4
Total	42	45	55	8	150
Discharged home... ..	10	23	23	—	56

43 patients can be regarded as recovered and they are all at present living at home; some of them have been well for as long as three years. All discharged patients have been followed up by personal interview or by correspondence with their relatives, family doctor, or with the patient himself.

32 patients come under the heading of "much improved" and 13 of them have been able to return to their families. In general this group includes patients who can now have parole, enjoy the amenities of the hospital and do useful work under supervision.

Altogether 56 patients of the "recovered" and "much improved" groups have been able to return home.

31 patients have "improved". Many were previously serious nursing problems and now take part in occupational and recreational therapy, or do simple work in the hospital or on the farm.

31 patients have "improved slightly" and this has usually meant the loss of certain troublesome features of their illness such as violent or impulsive behaviour, faulty habits or destructiveness; other symptoms persist.

9 patients may be regarded as "unchanged" and remain in approximately their pre-operative state.

These results are not final in many patients, since we can expect that our more recent cases will continue to improve. Periodical surveys of our case material indicate that improvement can continue for as long as three years after the operation. Similarly we appreciate that the possibility of relapse cannot yet be ruled out. Besides the evanescent post-operative improvement which sometimes occurs, some cases improved for a time and then relapsed—several, for example, went home for short periods. None of these was among our best cases and we have had no major relapses in patients who could be included in our "recovered" group. So far none of our surviving patients can be regarded as worse as a result of the operation. Our 4 fatalities occurred early in the series and we have had none among the last 120 cases.

DISCUSSION

These results are encouraging and the scepticism with which the operation was originally regarded in our hospital has given place to tempered enthusiasm for this new form of treatment in carefully selected cases. In achieving these results our experience has convinced us that re-education plays a major part in determining the quality of the remission. The conception that the injured cerebral tissues have their functions progressively taken over by other areas cannot be over-emphasized and should be the basis of our attitude towards re-education. Co-operation between medical officers, nurses, and occupational therapists is necessary and a scheme for the re-education of the individual patient should be arranged. I would go so far as to say that the operation should not be undertaken unless facilities exist for expert rehabilitation.

Our most considerable experience has been with schizophrenics and now we feel that the operation should be carried out in old-standing cases who fulfil the criteria I have outlined. It may be of interest to note in these cases we have found that a well-established periodicity of the symptoms is a favourable prognostic sign.

In earlier schizophrenics where tension is a prominent feature and where insulin and E.C.T. have been thoroughly tried one should not hesitate to consider the operation if clinical judgment indicates that the case is deteriorating and reasonable hope of a spontaneous remission can be ruled out. In our hospital the decision to operate is taken only after the case has been discussed fully at a meeting of the medical staff.

By far the best outcome was achieved in our small group of obsessional, 6 of our 7 cases have recovered, the seventh has improved and may yet recover. We feel therefore that a lifelong obsessional should have the benefit of the operation if psychotherapy has failed to relieve his condition and if his symptoms so grossly interfere with his existence that he cannot live an ordinary life. One has to be careful, of course, to exclude those cases where the obsessions are merely symptomatic of, or temporarily exaggerated by, an underlying endogenous depression. Our group of melancholics is small because the results of E.C.T. are favourable and only when patients relapse so frequently that they cannot live outside a mental hospital do we consider the operation advisable. In none of

our cases was the illness of shorter duration than three and a half years. 2 of our group of 8 melancholics recovered, 3 are much improved. Our one case of recurrent mania has had her operation too recently to judge the ultimate outcome but she has been consistently well during the ten weeks which have elapsed since her operation. Our experience with organic illnesses is too small to draw any conclusions but one of the two epileptics has improved in that her violent psychomotor equivalents are less severe, and the distressing agitation in the case of Parkinsonism has been relieved completely.

I may sum up by saying that the outstanding impressions gained from more than three years' experience of the operation are the excellent results in obsessional states, the encouraging results in chronic melancholia and above all, the remarkable change in outlook for the distressful cases of schizophrenia which form such a large proportion of the chronic population of our mental hospitals. The most urgent problem in regard to the operation appears to be the need for a systematic study of recovered cases, especially those who have had the treatment at an early stage of their illness in order to assess more accurately the degree of personality change which follows the lesion to the frontal lobes.

Dr. Jan Frank: *A review of 200 cases of leucotomy at Graylingwell Hospital, Chichester.*—The length of observation varies from eight months to three years. *Social recoveries* were regarded as those who are capable of independent management of their own affairs, occupy a post, have the type of work they had formerly, and are, at the same time, able to appreciate the enjoyments of life. It may be of interest to note in these cases we have found that a well-established periodicity of the symptoms is a favourable prognostic sign.

In earlier schizophrenics where tension is a prominent feature and where insulin and E.C.T. have been thoroughly tried one should not hesitate to consider the operation if clinical judgment indicates that the case is deteriorating and reasonable hope of a spontaneous remission can be ruled out. In our hospital the decision to operate is taken only after the case has been discussed fully at a meeting of the medical staff.

By far the best outcome was achieved in our small group of obsessional, 6 of our 7 cases have recovered, the seventh has improved and may yet recover. We feel therefore that a lifelong obsessional should have the benefit of the operation if psychotherapy has failed to relieve his condition and if his symptoms so grossly interfere with his existence that he cannot live an ordinary life. One has to be careful, of course, to exclude those cases where the obsessions are merely symptomatic of, or temporarily exaggerated by, an underlying endogenous depression. Our group of melancholics is small because the results of E.C.T. are favourable and only when patients relapse so frequently that they cannot live outside a mental hospital do we consider the operation advisable. In none of

definite before at least six months have elapsed after the operation. The mental state within this period, however stormy, or startlingly free from psychotic symptoms, has no relevance for the final outcome. The same applies to neurologic complications, organic confusional states, incontinence, perseveration. All these were more frequent by the posterior cut—only one, however, remained permanent. One patient developed an extrapyramidal permanent neurologic complication. Since operation, he has choreiform jerks resembling those of Huntington's chorea. (His mother died of some form of chorea.) He was refractory to the operation and is still an unrelieved paranoid schizophrenic. 15% of our cases had urinary incontinence which lasted more than two months, but in none did it remain a persistent disability.

18 patients had major epileptiform convulsions, usually one or two; 2 cases had six fits at short intervals. Although the E.E.G., according to Dr. Hill's personal communication, is normal three months after the operation, the great majority of our 18 cases first had fits six months after. 15 had posterior, 3 anterior cuts. After two to four months' anti-convulsive drug administration, no recurrence of convulsions was observed later than eight months after the operation.

A slight flabbiness of the innervation of the facial muscle—rendering the mimical expression less distinct than before—is in few a lasting sequelæ, although in many cases it is very marked during the days immediately after the operation. Bulimia is a relatively frequent post-leucotomy symptom in our patients, but disappears in from six to twelve months after. The ravenous appetite may also be responsible for some unusually rapid gains in weight. Some of our females showed hirsutic changes (7 patients), 4 of them previously had a pronounced facial growth of hair, but after leucotomy they developed a veritable beard. Nothing definite emerged concerning their menstrual cycle; some reported amenorrhœa following the operation.

Intelligence.—96 were tested. The impairment of simultaneous grasp, and of discriminative conceptual thinking, which we observed by psychometric testing, and from reports from the patients themselves, and the tendency to perseveration were not noticeable any more after the follow-up of ten months. In fact, apart from the age-group over 55, we could not detect any impairment of cognition or any intellectual deficit after the lapse of one year. We tested 96 cases with the Herring, Modified Stanford Binet, Raven's Matrices, Kohs' Blocks, Pass-along Tests, but could find no significant difference in their general intelligence, except that in the recovered cases their scores showed less scatter. Patients over 55 display a discrepancy of their vocabulary, verbal and performance scores—in some consisting of a difference of 15 (I.Q.) points to the disadvantage of performance; 10 out of 16 patients. We tested these cases also with Rorschach; we could not surmount, however, the difficulty of familiarity with the blots when shown before and after operation, so we found it impossible to utilize these in our findings with regard to post-operative personality changes.

None of the patients regained true insight in the full sense of the word, or is able really to appreciate what the operation was for, or its importance. The direct effects of the operation on psychic life are those on the personality. The specific change which was verified in the surveyed cases was a poverty, or entire lack of dreams, and a thinning, or disappearance of dereistic experience—they cannot daydream about their wishes, or be abstractly angry in a sustained fashion. They become, due to this emotional asymbolia, more plain, matter-of-fact like. In many ways it has a resemblance to slight senile personality changes. Owing to the emotional desensitization, the passions and conflicts which are expressed in their psychosis gradually shift out of focus: very similar to old men who can look serenely upon the follies of their youth. Similarly also, to senile personality changes, post-leucotomy patients do not like adventure, but want to remain in a more or less stereotyped routine of activities. The learning ability for new knowledge is, as some complain, reduced. In the old involuntal melancholic the paradox occurs that the desperate loneliness of oncoming senility is alleviated by reaching faster the state of a happy dotage. This is borne out, not only in the personality changes, but in the neurologic symptoms also: e.g. if they have had a tremor of the hands it gets worse after leucotomy. Their gait, too, becomes less steady.

We had no patient in this series who was worse after the operation. Whether the 3 improved cases who, more than a year after, still manifest frontal disinhibition and are unrestrained, selfish, family tyrants, are due to more extensively damaged frontal areas owing to anomalous placing of the cut, or some secondary changes, is impossible to say. The topographical variability of the incision, decisively proved by A. Meyer, is unavoidable with the present technique, and a grave drawback. In our series there was no clinical disadvantage accruing from the more anterior incision—but certainly much less spontaneity and loss of initiative—which is quite frequently observed in the posterior, more extensive cut.

Mortality.—We lost 5 patients directly attributable to leucotomy. 4 died of cerebral hæmorrhage, 1 of staphylococcal meningitis. The percentage is 2.5%. 3 died of intercurrent illness more than a year after the operation.

Relapses.—2 paraphrenics classified as recovered, relapsed; both after a year—one as a result of harassing environmental circumstances. 1 schizophrenic classified as improved relapsed after three months; an improved aggressive psychopath relapsed eight months after the operation.

SUMMARY

The clinical results of prefrontal leucotomy in 200 cases of chronic mental illness have been reported. The time of follow-up was seven months to three years. Out of 92 schizophrenics, 19 (20.7%) socially recovered; 28 (30.4%) improved; 45 (48.9%) remained unchanged. In certain types of schizophrenics, caution is expressed with regard to the

President—P. E. H. ADAMS, F.R.C.S.

[February 14, 1946]

Lesion of Left Macula.—VIOLET M. ATTENBOROUGH, D.O.M.S., for E. F. KING, F.R.C.S. Male, aged 52. Caretaker. First seen at Moorfields in February 1943. He complained of gradual loss of vision in the left eye. His right vision was then 6/6 and his left vision was 6/18. On examination he was found to have some fine pigmentary disturbance at his left macula.

In June 1943 his left vision had improved to 6/12. May 1944, his left vision had fallen to less than 6/60.

On examination.—There was a raised mass on the temporal side of the left macula and some pigmentary disturbance and oedema at the macula itself. About this time he was shown at one of the Society's meetings.

Since then he has been kept under observation and a series of drawings have been made. There are now hæmorrhages present below the sub-retinal mass. His vision is now: Right (with glasses) 6/6 and left (with glasses) less than 6/60.

Investigations.—W.R. negative. Report from E.N.T. Hospital negative. Urine normal. Blood-pressure 150/95.

Mr. J. H. Duggart said that in his view this was certainly inflammatory. It was a low-grade bilateral chorioïdo-retinitis central and peripheral. There were multiple small foci all round the periphery, definitely more than stippling within normal limits. There were also early changes around the macula consisting of ill-defined overlapping yellow dots. He had watched for some years cases like this, in which, in the earlier examinations, one eye was not involved but became involved after two or three years. He thought that this condition was inflammatory and that the prognosis was bad.

Mr. E. F. King said that he took a different view from Mr. Duggart. In his opinion the changes were degenerative, not inflammatory.

Mr. Eugene Wolff thought that this was a case of disciform degeneration of the macula most probably due to hæmorrhage from the choriocapillaris. The patient was rather younger (52) than the classical type but he did not think that mattered.

The President said that if the case was ten or fifteen years older there would be no doubt that it was a vascular degenerative condition, but some people did degenerate earlier, and he thought that this might be one of those cases.

Tuberculosis of the Conjunctiva.—E. F. KING, F.R.C.S.

Girl, aged 14 years. Bacteriological examination had shown a large number of tubercle bacilli in the conjunctival ulcer in the left upper fornix. Opinion was evenly divided as to whether an attempt should be made to do anything surgically—local removal of the ulcer—or whether reliance should be placed only on sanatorium treatment. Calciferol had been suggested.

The lungs were normal and there were apparently no other tuberculous foci in the body.

Mr. C. B. Goulden said that in cases of tuberculosis of the conjunctiva the lesion should be removed if it were not too big and if not too much conjunctiva had to be sacrificed. Otherwise he would suggest general radiation with ultraviolet light, and tuberculin. Mr. S. H. Browning, who had had a large experience of these cases, said that that had been the plan he had followed. In the speaker's view, in this case, the lesion was too big to be dissected away; it would involve too much sacrifice of conjunctiva.

Mr. Affleck Greaves agreed that excision would involve too much sacrifice of conjunctiva. He suggested that a course of treatment with calciferol might be tried in view of the successes obtained with this drug in lupus cases. Also local treatment with ultraviolet rays by means of a quartz applicator might be beneficial, care being taken to protect the eye with a contact shield.

Mr. Frank Juler had seen this case at hospital and he was in favour of excising the ulcerated area, as it seemed to him that nearly all of it could be got away. With a primary tuberculous lesion as complete removal as possible should be the better procedure. His feeling was in favour of excision, to be followed by radiation of the regional glandular enlargement, and general treatment on sanatorial lines.

Mr. P. M. Moffatt had seen a similar case just before the war. It was decided to send the patient away to a sanatorium, and when he came back he was, as far as could be ascertained, perfectly cured.

A member said that he would strongly suggest tuberculin treatment.

Mr. King thought the essential lesion was very localized and the follicular reaction secondary.

JUNE—OPHTH. 1

indication of operation. The importance is stressed of painstaking personality studies and also of clinical differentiation. The affective disorders and paraphrenics responded best to the operation. From 16 cyclothymics, 12 (75%) socially recovered. From 36 involuntional melancholics, 24 (66·7%) recovered. Among 38 paraphrenics, 22 (57·9%) socially recovered. A small number of chronic obsessional neurotics underwent the operation: 3 out of 4 recovered. In 11 mostly oligophrenic aggressive psychopathies operated on, the results were disappointing: 1 socially recovered, 7 were somewhat improved, the rest remained unchanged. No cases were considered worse. It is assumed that the emotional asymbolia observed after leucotomy determines mainly the personality changes which have the curative effect in chronic mental illness. The general intelligence is not affected by the operation in patients less than 55 years of age. The mortality rate was 2·5% (4 of cerebral hæmorrhage, 1 of staphylococcal meningitis).

My thanks are due to Dr. J. Carsc, Medical Superintendent.

Dr. William Sargent (*Sutton Emergency Hospital*) discussed a series of over 20 cases of intractable neurosis and psychosis which had had this operation without being admitted to a mental hospital. Obsessional symptoms, rumination and tension were generally relieved to a variable extent. Some cases had been able to return home in as little as a fortnight after the operation while others needed skilled rehabilitation in a neurosis centre. The operation should be extended beyond the confines of a mental hospital atmosphere and the chronic type of mental hospital patient. But psychiatrists had to be certain from a first-hand working knowledge of all other treatments, both physical and psychological, that these had been properly used or were unlikely to succeed.

Referring to Professor Freeman's use of leucotomy for the relief of unbearable pain, he wished to report what might well be the first case in which a modified leucotomy had been used in a case of intractable dermatitis, resistant to all previous treatments for many years. The patient was obsessed with her condition and the more she worried the more she scratched. She had previously been in a mental hospital for short periods because of her agitation, and was thought a suicidal risk at the time of operation because of her persistent suffering. As a result of the operation she lost her tension and scratching. Her dermatitis subsided. With minor ups and downs this remarkable improvement had been maintained for over two years. Only a modified operation was done and no obvious mental deterioration was observed. She still kept house and led an active life. It might be necessary to do a more thorough operation on similar cases in the future because recently this patient's obsessional anxiety was returning with increased skin irritation and scratching. This was probably due to gradual reformation of basic personality patterns described by Professor Golla. In two cases of obsessional neurosis, a second operation had been more successful where a limited first operation had resulted in improvement with a return of symptoms.

Dr. U. M. Hickman, whilst fully agreeing that prefrontal leucotomy should not be performed until full courses of insulin and E.C.T. had been tried, felt that leucotomy should not become an operation primarily to be carried out in general rather than mental hospitals.

At Warlingham, where they had performed just under 100 leucotomies, all but three had both insulin and E.C.T. and in most cases combined treatment. The three exceptions were contra-indicated by physical illness, pulmonary tuberculosis in two cases, spinal caries in the other case.

After the operation much care and thought were spent on the rehabilitation of the patient, adapting the routine to suit each individual case. They had found that suitable occupational and recreational therapy played an important part in the re-socialization of these patients, and one of the most useful methods of employment, in suitable patients, was to allow them to work in the patients' canteen and club—this provided social contacts and developed a sense of responsibility. Dr. Moore had already stressed the importance of rehabilitating the post-leucotomy patient. Surely the whole sequence of pre-operative treatment, the insulin, E.C.T., &c., the operation and the rehabilitation should be carried out by the same medical officers and nursing staffs, if a proper assessment of the patient's responses and degree of return to normality were to be observed, and this was only possible in a mental hospital.

Dr. Isabel Wilson suggested that photographs before and after leucotomy might be taken with similar lighting, dress and background, and that clinical notes after should if possible be comparable with those before, and not be confined to fresh aspects of the case.

Mr. P. M. Moffatt had seen a similar case just before the war. It was decided to send the patient away to a sanatorium, and when he came back he was, as far as could be ascertained, perfectly cured.

A member said that he would strongly suggest tuberculin treatment.

Mr. King thought the essential lesion was very localized and the follicular reaction secondary.

JUNE—OPHTH. 1

DISCUSSION: INDICATIONS FOR THE TECHNIQUE OF INTRACAPSULAR EXTRACTION OF CATARACT

Dr. O. M. Duthie (Manchester): Opinions on the advisability of intracapsular extraction still appear to be divided. I think, however that whatever the merits or demerits of extra- or intra-capsular operation may be, it is right that any surgeon should choose that type of operation which suits him and his fingers best and in which he feels he can produce the best results for his patients.

Because of this, for the last eleven years I have practised only Sinclair's method of intracapsular extraction by tumbling. Sinclair's technique can certainly be mastered by any surgeon of reasonable ability, though judgment of its value can only be based on the end-results of the operative and post-operative complications as contrasted with other methods. Apart from a few exceptions, with which I shall deal later, this operation can be performed on all types of cataract.

It is a matter of great regret that no textbook and no article of importance fails to stress the difficulty of the operation in the hands of the young surgeon (or, for that matter, any other surgeon)—this is untrue and puts every young man off before he starts. Far better would it be to let him commence with the idea that nothing unusual is required except a great attention to detail and this should apply equally to every eye operation. I am here concerned only with two aspects of the problem—the method and the indications.

Dr. Duthie went on to discuss, with the aid of diagrams, the details of the technique of Sinclair's tumbling method, emphasizing the details of local anaesthesia, lid sutures, full iridectomy, puncture of an intumescent lens, the correct rocking movements after grasping the capsule, counter pressure from below after dislocation, and final toilet. The technique was further illustrated by means of a coloured cinematograph film.

Finally, the indications were discussed at length, the opener emphasizing his view that all types of cataract, over the age of 30, and unless general conditions contra-indicated operation, were suitable for intracapsular extraction. Particularly did this apply to high myopes, diabetic and secondary cataracts and immature cataracts of all types.

Loss of vitreous was discussed in full and finally, an analysis was given of 1,000 consecutive intracapsular extractions, with their end-results and surgical complications.

Mr. John Foster (Leeds): As my instructors invariably employed the extracapsular technique, I followed suit in independent practice from 1912-1937.

By then, personal observation of intracapsular extraction with forceps in Continental clinics had convinced me that the dangers of the method had been exaggerated. Later observation in Edinburgh confirmed this. Since July 1937 I have performed or helped my assistants perform about six hundred intracapsular extractions. Naturally, at first vitreous and iris prolapse and the ruptured capsule presented greater problems than with the extracapsular method. I tried expedients advised by various intracapsular operators to counter them, retaining those which were effective.

The technique finally adopted has been static too short a time to offer statistical proof; nevertheless, as these procedures have so greatly improved my control over difficulties, I feel that they may be of interest to anyone thinking of changing to the intracapsular method.

There are certain minor difficulties which are severally negligible, but collectively upsetting to patient or surgeon. As Cruise has taught, both should be "surgically comfortable" for a good result.

Simplification of technique and instruments may ensure this in a day of rapidly changing subordinate staff. I avoid mentioning knives in this connexion, as this subject requires a complete lecture to itself.

Pre-operative period.—Patients are upset by too much treatment before and after operation, and I would omit even the most traditional procedures unless they have an experimental or controlled clinical basis.

I would agree in stigmatizing dentiveses (Evans, 1939), hæmostatics (de Voe, 1942) and routine dental treatment (Wright, 1937) as useless, and have not employed them for ten years. I except a transfusion for pernicious anaemia, and a few days' pre-operative rest in the ward (if quiet) for very high blood-pressure.

I have admittedly not tried pre-operative phlebotomy as a preventative of expulsive hæmorrhage, as although highly regarded in Europe, its effect on the blood-pressure is only transient (Miller, 1926). For several years I have disregarded pre-operative

cultures (Foster, 1941), although they are taken in the routine manner (Mayweg, 1911; Schönemann, 1911; Lindner, 1915). As will be noted from Table I my infection rate (Clinic A) is lower than that of my colleague (Clinic B) in the same hospital, who operates on "clean" cases only. Of my own infected cases four were "clean" and of the four "dirty" ones two had infected lacrimal sacs that routine syringing (later instituted) would have detected.

TABLE I.

		Number	"Dirty" culture	Post-operative infection	%
Clinic A	...	358	22	8	2.21
Clinic B	...	200	—	5	2.5

That the weakness of the culture, up till now, as an indicator of post-operative infection is probably in part due to misconception of the relative pathogenicity of organisms and in part due to the inefficacy of antiseptics subsequently used, is shown by the results of Dunnington and Khorazo (1945) who found that the 11 infected cases occurring among 2,504 operations did not arise from pneumo- or strepto-cocci, but all occurred among 529 cases containing a particular *S. aureus*. Subsequently, by the use of antibiotics in such cases, they obtained the striking result of 663 cases with no infection, as compared with 730 cases treated by a conventional antiseptic in which 13 became infected.

The theatre.—Among the minor troubles of the theatre is the face mask. For so short a working distance it is essential to cover the operator's nose (I. Walker, 1930, and J. S. Davis, 1934) and unless it is short enough in front and provided with a chinpiece to keep it half an inch below the orbital margin, it is liable to rise above and obstruct the view [pictures shown]. An iron wire fitting close to the bridge of the nose is also useful to prevent "steaming", if the mask has the modern cellophane insert (Blatt and Dale, 1930) and the operator wears glasses.

Unless the operator wears gloves, long sleeves on the gown are a nuisance, best overcome by attachment of an orthopaedic stockinet cuff. One cannot always get short sleeved gowns in a general hospital.

Preparation of the patient: Soaping the eyelids in the theatre is waste of time; it takes three minutes "scrubbing" (literally) to remove the "transient" and two and a half hours' scrubbing to remove the "resident" flora of the skin (Price, 1938a; Durward, 1945).

Washing is best done by the patient in the conventional manner in the ward (Price, 1938b). 2% cetavlon which is virtually non-irritant is a better antiseptic than iodine round the eye, and being a "cationic soap" would permit of "washing" in a grossly dirty patient.

I doubt if irrigation does more than remove dirt mechanically, and have used normal saline for this purpose in the theatre for years.

The spouts of undines frequently break during repeated sterilization, and the lotion is difficult to keep at body temperature during a long list.

The American thermostatically controlled solution cupboard holding a number of filled, sterile undines is the best answer to this problem. My attempt to construct one here during the war failed, as I could not get adequate thermostats, or heating elements to give convection with a smooth, sterilizable surface.

The sterile towels to cover the patient's face are as a rule inadequate (allowing sutures to trail on the skin), complex, or requiring a clip. In Scandinavia and in Prague (Elschnig, 1922) a simple perforated towel with a selvaged opening avoids these difficulties. The mesh must be fairly open to allow the patient to breathe through it, and the opening at least 6 by 5 cm. to allow about 1 cm. shrinkage to the size of the orbit (5 by 4 cm.) (Richet and Luschka, 1922) with use.

The temperature of most ophthalmic theatres is too high as a rule for operations performed under local anaesthesia; a swing door to the sterilizing room may control this.

The lighting of cataract operations is a major problem. The fewer the people round the table the better, and the somewhat shaky nurse to whom the Hammer lamp is delegated is not a valuable addition.

Failure to use a new bulb, or to obtain correct centring (by an even chromatic edge to the disc of light) may reduce the already moderate illumination of a Lister lamp to a lower level. Table II gives the (makers') comparative figures showing the superiority of the scialytic lamp in this respect.

TABLE II.

		Dist.	Circle	Fixation	Intensity—f.c.
Lister	...	34 cm.	9 cm.	Shaky	86-148 (centring effect)
Scialytic (36 in.)	...	117 cm.	25 cm.	Firm	600 (75 in shadow of the hand)
Scialytic (18 in.)	...	105 cm.	25 cm.	Firm	1,000 (300 in penumbra of focus)

The makers' figures are given here, as my own observations with a photometer on lamps in use for some time gave lower figures. By holding the Lister lamp more closely (as can be done in capsulotomy) the illumination can be raised above 500 f.c. and avoidance of the reflex has certain advantages. So short a working distance is obstructive during lens extraction.

Syringes.—Some makes of syringe leak at the junction of syringe and needle mount, unless held together by two hands. This means that the forceps holding the tissue fold for injection have to be held by an assistant.

The "Luer-Lok" syringe prevents this leakage, and ensures one-handed use. Backward leakage may occur from rusting of the needle bore (much reduced by drying after use with the pneumatic needle dryer of Brunett and Flagg), or dissolution of a glass piston by alkaline boiling. This last requires a new syringe, as leakage deprives one of all idea of the volume of fluid injected behind the eye.

I have been unable to obtain a $1\frac{1}{2}$ in. "Luer-Lok" (American) needle in less than 23 gauge (rather too coarse for retrobulbar use) during the war, and as the exchange difficulty may persist it is interesting to know that a 26 gauge by $1\frac{1}{2}$ in. needle can be fixed in the original hub.

When a needle fails to perforate the skin, this may be due to a leathery skin, or to a needle defect. As the bore rusts before the exterior, if the needle is patent it is almost invariably due to a bent point. This is best detected by running the back and front of the point lightly over the finger-tip when the hook-like point catches in the papillæ. Such needles are most traumatizing. It should be noted, however, in these days of shortages, that they can be reclaimed later by pushing obliquely through a cork and rubbing on an Arkansas oil-stone.

The operation: Difficulties of access and vitreous loss.—I have not found vitreous loss to be the bugbear claimed with this method. I believe the method of access closely related to it. No speculum will fit all eyes adequately. The exposure I have found most helpful where the eye is not strongly upturned after retrobulbar injection, is the Gomez-Marques' (1940) superior rectus suture used without a speculum and with one or two retraction sutures in the lower lid. There is adequate access in spite of the slight "tenting" of the upper lid. If the superior rectus is very active, the suture is removed, and a big canthotomy and traction on the upper lid suture precede the section.

Capsular difficulties.—The frequency of taut, ungraspable capsules is reduced by the manoeuvre of Kirby (1936, 1941) (fig. 1). Pressure below the limbus at 4, 6, and 8 o'clock with the point of the lens expressor inwards for 2 mm. ruptures the zonule and renders the lower part of the capsule slack, and more easily grasped by subsequently applied forceps.

FIG. 1

FIG. 2.

FIG. 3.

Where this fails the manoeuvre invented experimentally by Csillag (1936), used clinically by Traquair in 1941, and described in detail by the previous speaker, is employed.

Iris prolapse.—If prolapse of the iris recurs after reposition, as there is no danger of incarceration of the capsule, a complete iridectomy is justifiable.

Sometimes, however, this can be avoided by inserting a drop of 1% sterile eserine sulphate, and compressing the section as shown (fig. 2) with a lens expressor for a minute until the pupil contracts strongly. A peripheral iridectomy is then adequate.

Bandaging.—The safest, most rapidly applied and removed dressing of which I am aware, is Gluck's shield, held by two strips of elastoplast. I have used it without and with a minimum of dressing, so that all pressure is taken on the nose, brow, and cheekbone. A dressing which raises the shield from the bony prominences transmits any pressure on the shield to the eye and not to the facial bones.

A slight elevation of the shield permits division of the elastoplast which is left attached to the face and shortens the time of "dressing" enormously (fig. 3).

Convalescence.—Some relaxation of the traditional confinement to bed is due here. If at the first dressing (forty-eight hours) there is no evidence of prolapse or hyphæma, I allow my patients to get up. Mental disturbance and chest trouble are now much less frequent.

There are two obstructions to this policy. Few English hospitals have an adequate day room attached to the ward, nor have they adequate accommodation for patient's clothes, which are liable to be stolen.

As the pupil is clear and the eye free from inflammation in most cases, it is possible to refract them before discharge. Hamblin's "temporary cataract trial frame" glazed with a "flat" cylinder to which the appropriate plano-sphere for distance or reading can be clipped, allows the patient to use the eye at once, and has accustomed him to peripheral distortion by the time the refraction is stable. I have had several patients who preferred this form of frame to the conventional type.

On discharge the patient and his doctor seek information on his conduct during the next few weeks. The following instruction sheet which can be modified by erasion for an intra-ocular operation, saves a great deal of questioning and correspondence, if given to the doctor, and the relatives, a few days prior to leaving hospital.

Date.....

INSTRUCTIONS FOR M.....
FOR TREATMENT OF THE EYES AFTER OPERATION.

- (1) The edge of the eyelids are to be bathed every morning with a little piece of cotton-wool dipped in warm boracic lotion, to remove the discharge.
- (2) 1% atropine ointment should be inserted into the operated eye every morning after bathing.
- (3)should be inserted into the unoperated eye every morning after bathing.
- (4) No reading, bending, or walking about alone should be attempted, for fear of causing a hæmorrhage into the eye.
- (5) The metal shield (dark glasses) should be worn at night and during the day.
- (6) Walks out of doors if accompanied, or a ride in a motor car, are permitted, so long as the weather is fine.
- (7) The next appointment is for

In conclusion, may I say I am increasingly impressed with the rapid convalescence of the intracapsular as compared with the extracapsular extraction.

Mr. F. A. Williamson-Noble said that Mr. Duthie had omitted to describe his useful manoeuvre of retracting the upper lid with a squint hook at the time of extracting the lens. In cases of cataract secondary to iritis with posterior synechiæ, did he just trust to wobbling the lens from side to side to free the adhesions, or did he separate them first with an iris repositor? The anonymous cataract glasses which Mr. Foster had described were, he thought, invented by himself; he had suggested the idea to Hamblin's a few years ago, and they had been making them for some time now.

Mr. M. Klein showed two drawings illustrating dissection with due regard to the position of the facial nerve.

The correct point for the injection, when the middle portion of the facial nerve is used for palpebral akinesia (O'Brien's method), lies at the junction of the middle and upper third of the distance between zygomatic arch and angle of the mandible on the condylar process.

Mr. M. D. Thakore asked whether the procedure described was the right one in a nervous patient, who was rather less helpful than others. Was it always essential that there should be a conjunctival suture? For over fifteen years he (the speaker) had used coagulen (Ciba) instead.

The makers' figures are given here, as my own observations with a photometer on lamps in use for some time gave lower figures. By holding the Lister lamp more closely (as can be done in capsulotomy) the illumination can be raised above 500 f.c. and avoidance of the reflex has certain advantages. So short a working distance is obstructive during lens extraction.

Syringes.—Some makes of syringe leak at the junction of syringe and needle mount, unless held together by two hands. This means that the forceps holding the tissue fold for injection have to be held by an assistant.

The "Luer-Lok" syringe prevents this leakage, and ensures one-handed use. Backward leakage may occur from rusting of the needle bore (much reduced by drying after use with the pneumatic needle dryer of Brunett and Flagg), or dissolution of a glass piston by alkaline boiling. This last requires a new syringe, as leakage deprives one of all idea of the volume of fluid injected behind the eye.

I have been unable to obtain a $1\frac{1}{2}$ in. "Luer-Lok" (American) needle in less than 23 gauge (rather too coarse for retrobulbar use) during the war, and as the exchange difficulty may persist it is interesting to know that a 26 gauge by $1\frac{1}{2}$ in. needle can be fixed in the original hub.

When a needle fails to perforate the skin, this may be due to a leathery skin, or to a needle defect. As the bore rusts before the exterior, if the needle is patent it is almost invariably due to a bent point. This is best detected by running the back and front of the point lightly over the finger-tip when the hook-like point catches in the papillae. Such needles are most traumatizing. It should be noted, however, in these days of shortages, that they can be reclaimed later by pushing obliquely through a cork and rubbing on an Arkansas oil-stone.

The operation: Difficulties of access and vitreous loss.—I have not found vitreous loss to be the bugbear claimed with this method. I believe the method of access closely related to it. No speculum will fit all eyes adequately. The exposure I have found most helpful where the eye is not strongly upturned after retrobulbar injection, is the Gomez-Marques' (1940) superior rectus suture used without a speculum and with one or two retraction sutures in the lower lid. There is adequate access in spite of the slight "tenting" of the upper lid. If the superior rectus is very active, the suture is removed, and a big canthotomy and traction on the upper lid suture precede the section.

Capsular difficulties.—The frequency of taut, ungraspable capsules is reduced by the manoeuvre of Kirby (1936, 1941) (fig. 1). Pressure below the limbus at 4, 6, and 8 o'clock with the point of the lens expressor inwards for 2 mm. ruptures the zonule and renders the lower part of the capsule slack, and more easily grasped by subsequently applied forceps.

FIG. 1

FIG. 2.

FIG. 3.

Where this fails the manoeuvre invented experimentally by Csillag (1936), used clinically by Traquair in 1941, and described in detail by the previous speaker, is employed.

Iris prolapse.—If prolapse of the iris recurs after reposition, as there is no danger of incarceration of the capsule, a complete iridectomy is justifiable.

Sometimes, however, this can be avoided by inserting a drop of 1% sterile eserine sulphate, and compressing the section as shown (fig. 2) with a lens expressor for a minute until the pupil contracts strongly. A peripheral iridectomy is then adequate.

Bandaging.—The safest, most rapidly applied and removed dressing of which I am aware, is Gluck's shield, held by two strips of elastoplast. I have used it without and with a minimum of dressing, so that all pressure is taken on the nose, brow, and cheekbone. A dressing which raises the shield from the bony prominences transmits any pressure on the shield to the eye and not to the facial bones.

A slight elevation of the shield permits division of the elastoplast which is left attached to the face and shortens the time of "dressing" enormously (fig. 3).

[February 12, 1946]

DISCUSSION ON PENICILLIN IN THE TREATMENT OF SYPHILIS

Dr. James Marshall (*lately Adviser in Venereology to the War Office*): Until 1943, when it was demonstrated that penicillin possessed spirochaetocidal properties, the adequate treatment of syphilis had always been attended by danger of toxic effects from the remedies used. These dangers were enhanced by any treatment method in which a rapid curative effect was sought by increasing dosage or by reducing the time in which a therapeutically effective dose of the selected drug was given. The war and consequent increase of syphilis in a mobile service and civilian population hastened research in the methods of rapid treatment of syphilis, as even in a disciplined community such as the British Army the long-term treatment of syphilis by neoarsphenamine and bismuth was satisfactorily completed in only about 50% of cases. This treatment was further impaired, especially in the Army, by an epidemic of the so-called post-arsphenamine jaundice.

In France, of recent years, a considerable number of venereologists almost abandoned the arsphenamines in favour of bismuth (Gaté and Cuilleret, 1945) because of a fear of the grave risks sometimes encountered. This retreat from the arsenicals was sufficiently great to call for a plea for reason in the matter by Milian (1945).

The advent of penicillin, which appeared to promise cure of early syphilis in a short space of time and without producing any dangerous toxic effects, was therefore hailed with great enthusiasm. It needs at least five years to assess the value of any method of treating early syphilis, and therefore the dosage and treatment schedules recently employed for penicillin have of necessity been experimental. The experiments have, however, been on a large scale and allow of certain conclusions and assumptions.

EARLY SYPHILIS

The treatment of early syphilis has so far been carried out mainly by multiple intramuscular injections using aqueous solutions of penicillin. With this method, almost independent of the total dosage used, immediate results are the same—*Sp. pallida* disappears from surface lesions in about twelve hours, lesions heal quite rapidly, and positive serological reactions tend to reverse towards negative. Appraisal of results depends, therefore, on the appearance of evidence of clinical or serological failure after weeks or months. The largest experiments with penicillin alone were done on the plan of giving 60 injections, one every three hours, over seven and a half days. Moore (1945) had indicated that with a total dose of 60,000 units the failure rate is 100%; with 300,000 units about 75%; with 600,000 units about 40%; and with 1,200,000 units about 15 to 20%. Very large numbers of cases have been treated in the Allied Armies by 2,400,000 units penicillin over seven and a half days. Pillsbury (1945) stated that in the American Army in Europe the infectious relapse rate was between 1 and 2% in some 5,000 to 8,000 men so treated. In the same series, in some hundreds of patients, serum tests were

Mr. A. B. Nutt asked with regard to the post-operative treatment, how soon were the patients got out of bed; he also asked what was the material used by Mr. Foster to seal the face masks to the skin.

With regard to the treatment of complicated cataract, he remembered seeing a case done in Oslo in 1937 and had been impressed by the way in which the surgeon separated the iris from the lens before extracting the lens.

Mr. Foster had mentioned the slipping of masks: if the mask were adjusted so that the upper tapes went round the ears from below, and then tied on the top of the head, it would not slip up over the eyes.

Mr. Foster, in reply, said he did not seal the occlusive towel to the skin.

He found mask tapes placed under the ears and over the forehead were uncomfortable if tight, and liable to slip if looser. The problem of steaming of glasses was not a personal one to him yet, as he wore no optical aid apart from a Bishop Harman loupe on rare occasions.

He believed that the claim that myopes did well with intracapsular extraction was not entirely novel but that it had already been made by Elschmig. (He had been unable to verify the reference).

It appeared to be implied by one previous speaker that a peripheral iridectomy was difficult after the lens had been extracted intracapsularly; this was not so. It was quite simple, but where there remained the slightest visible tendency to prolapse after eserine, he himself always performed a complete iridectomy, as there was no risk of capsular incarceration.

Although an admirer of Kalt, and a frequent visitor to the "Quinze Vingt" in peacetime, he had never been able to get apposition by corneal sutures, with comparable accuracy. After two cases of epithelial downgrowth, which he blamed on the "overlap" he now copied Lindner and employed conjunctival sutures unless there was exophthalmos.

He was interested to hear that patients might get up before the second day, as not long before his own appointment to the Leeds Infirmary restless cataract patients had been immobilized for several days after operation by a towel over the forehead passed under a sandbag by each temple. Long before this it had been conventional on the Continent to sit uncomplicated cases in a chair forty-eight hours after operation. Eventually he thought even conservative nursing staffs would welcome the shorter period in bed, as there were fewer chest and mental complications, the patients were more comfortable, and nursing was easier.

He suggested that the probable reason the patients were "so good" at Manchester, was that they were not upset by pre-operative treatment. The more they received the more excited they became. Repeated postponement on bacteriological grounds was worst of all. If patients could walk straight from out-patients into the theatre, they would probably behave if possible even better.

Dr. Duthie, also in reply, said that Mr. Williamson-Noble had raised the question of secondary cataract. He always freed the iris with the iris repositor before he proceeded to extract. Having lost many of the hospital records owing to enemy action, he circularized the patients with a view to obtaining their later history. The best letter he received was from a relative who wrote: "Thank you for inquiring about grandpa." He died last Tuesday. Until the day of his death he was drawing the blind pension. He looked this man up in his records and found that the last entry was that he had 6/9 vision. He thought he was entitled to say that that was not the kind of case that came into his series.

He had no hesitation in doing a full iridectomy if necessary.

Dr. Sinclair had taught him to get his patients up after forty-eight hours, and this was done provided the eye was quiet and the anterior chamber reformed. On the tenth day the bandages were removed and a shade was worn. The bandage over the unoperated eye was removed after twenty-four hours. He, like Mr. Foster, had been brought up on the sandbag and towel method, but he insisted that his patients must be nursed in the most comfortable position.

He agreed that the more pre-operative treatment that was given the worse did the patients become. He was brought up in a great school of clinicians, and when he started with patients they were purged and Heaven knew what else!

A question had been asked about the suture. The object of it was to bring the edges of the wound into apposition.

He added that what he had learned most from that discussion was in Mr. Foster's quotation of Sir Richard Cruise's remark about being "surgically comfortable", that was the whole secret.

satisfactory method of treatment I was guided by the American observation that there was probably a synergistic action between penicillin and arsenoxide. Dr. F. R. Selbie, whose work on animal syphilis is well known, advised me also, and the original scheme which we evolved consisted of the administration of 2,400,000 units penicillin over seven and a half days, beginning at the same time, 14 intravenous injections each of 0.09 gramme Neohalarsine or 0.06 gramme Mapharside, over twenty days. The arsenical injections were given on two days out of every three, a method known to be almost free of dangerous toxic effects.

This scheme was altered in order to reduce the time spent in hospital and the method I have used for the last nine months consists in giving 2,400,000 units penicillin in seven and a half days and 10 daily injections of 0.09 gramme Neohalarsine or 0.06 gramme Mapharside. Arsenical toxic effects are rare, and if they occur arsenical treatment ceases and the total dose of penicillin is increased to 4,000,000 units (100 injections of 40,000 units). This routine has been adopted by Colonel Copping, Consulting Physician Canadian Army, for Canadian soldiers requiring a rapid effective treatment before repatriation.

So far, 360 cases have been treated by these methods; 120 with penicillin and 14 injections of Mapharside or Neohalarsine, and the rest with penicillin and 10 injections of Mapharside.

Only about one-third of this number has been successfully followed over four to six months after completion of treatment, but so far there have been 3 cases of mucocutaneous relapse, 1 case of possible reinfection, and another of indubitable reinfection, and no case of serological relapse. Of the 3 cases of relapse it is interesting to note that 2 had previously been treated unsuccessfully for syphilis; one with 2,400,000 units penicillin, and the other with nearsphenamine and bismuth.

Major S. M. Laird quite independently, but for the same reasons as I, began about the middle of 1945 to supplement penicillin treatment with arsenoxide (400 mg. Mapharside) and bismuth (1 gramme). His successor, Major Muirhead, has told me that over 500 cases have now been so treated but a significant follow-up has not been possible. Three cases of surface relapse have, however, been seen among those followed.

These results suggest that combined therapy with penicillin and arsenoxide, although not attaining complete efficiency, is an improvement on treatment with 2,400,000 units penicillin alone. Combined therapy, judging by early results, is probably in the same order of effectiveness as the "20 day" arsenoxide and bismuth treatment and is, if done in good circumstances, almost without danger. In my series there have been a few cases of minor toxic arsenical effects and one case of encephalopathy which recovered. Three cases of jaundice, occurring about 100 days after treatment, have been noted. In Major Laird's series there was no case of arsenical toxicity.

For the treatment of patients who have relapsed after treatment with penicillin alone, I now use 4,000,000 units penicillin and a daily injection of 0.06 gramme Mapharside or 0.09 gramme Neohalarsine for ten days.

I recently began two large-scale experiments in penicillin therapy for early syphilis in the Army. The routine treatment in Army hospitals now consists either in 2,400,000 units penicillin with a daily injection of arsenoxide (Mapharside 0.06 gramme or Neohalarsine 0.09 gramme) for ten days, or in 4,000,000 units penicillin alone. 1,000 cases are to be treated by each of these methods and the results of a follow-up on such numbers should yield information of some value.

Other methods.—The great drawback with penicillin has been the necessity for hospitalization and in civil practice this has meant that its use has been curtailed. Until now, for my civilian patients at the London Lock Hospital, my scheme has been to begin treatment with nearsphenamine and bismuth on diagnosis and to have patients admitted to hospital for a week for 2,400,000 units penicillin as soon as possible. The arsenical and bismuth treatment continues in hospital and after discharge for a total of ten weeks, i.e. the equivalent of one standard course. I have only treated about a score of cases in this way in the last year, so I cannot make any assumptions about the efficiency of the method.

Ambulant treatment with one daily injection of penicillin in beeswax oil mixture is at present on trial and early results will no doubt be available in a few months. Lourie (1945) and co-workers have described a rapid ambulant method in which 600,000 units penicillin in aqueous solution are administered intramuscularly every hour for three doses on five successive days. The series is very small but the results are good. Lloyd-Jones and Maitland (1945) have also reported good results in ambulant cases using

negative at the end of six months in 98% of seronegative primary cases, in 87% of seropositive primary cases, and in 72% of secondary syphilis cases.

My own experience in a relatively small series of cases similarly treated was not quite the same. Of 67 cases no less than 10 could be classified as treatment failures at the end of a six months' follow-up, surface relapses predominating. (Table I.)

TABLE I.—EARLY SYPHILIS TREATED WITH 2,400,000 UNITS PENICILLIN AND FOLLOWED FOR SIX MONTHS.

(Military Isolation Hospital, London.)

Primary	sero-negative	17 (of which 2 relapsed)	Analysis of relapse cases :	Cutaneous	...	5
"	sero-positive	38 (of which 4 relapsed)		Muco-cutaneous	...	2
Secondary		12 (of which 4 relapsed)		Serological relapse	...	1
	Total	67 (of which 10 relapsed)		Sero-resistance...	...	2
						10

That this was not an isolated phenomenon, due perhaps to faulty technique, is indicated by the results in a series treated at the Military Hospital, Preston (Table II), and followed for six months. (Major Muirhead kindly extracted these results.) Further, Major McPhater has indicated to me that the failure rate among cases so treated at Military Hospital, Peebles, was over 10%.

TABLE II.—EARLY SYPHILIS TREATED WITH 2,400,000 UNITS PENICILLIN AND FOLLOWED FOR SIX MONTHS.

(Military Hospital, Preston.)

Sero-negative syphilis	29 (of which 7 relapsed)	Analysis of relapse cases :	Muco-cutaneous	...	14
Sero-positive syphilis	70 (of which 9 relapsed)		Unsatisfactory serological response	...	2
Total	105 (of which 16 relapsed)				16

A recent check at the Central Syphilis Register at the War Office showed that in 270 cases of early syphilis, treated with 2,400,000 units penicillin and followed over six months, the failure rate was about 8%. At the same time a check was made on the same number of cases treated by the "20 day" arsenoxide and bismuth method, and the failure rate was only 2%. Dr. J. E. Moore, in a personal communication, has told me that the failure rate was 7% in a large series of cases followed for eight months after similar treatment with penicillin. Finally, in the American lay Press (Shalett, *Look Magazine*, 13.11.45) it has recently been stated that, judging from Army records, some 10 to 15% of cases of early syphilis will relapse in an infectious form in three to nine months after treatment with 2,400,000 units penicillin.

Relapse and treatment failure.—Relapse or failure of treatment may be manifested in a number of ways.

(a) *Surface relapse*: Cases are sometimes seen where the chancre fails to heal completely and later breaks down again. Oftener the chancre heals completely, but, after a latent period, reappears on the original site and may then be accompanied by signs of secondary syphilis. Sometimes relapse phenomena are entirely "secondary" in type, the primary lesion remaining healed. Evidence of serological relapse often, but not always, precedes or accompanies surface relapse.

Relapse lesions are often small and discrete and may escape notice by the patient. The ano-genital area should always be inspected closely at routine follow-up examinations as it is a common site for relapse phenomena of the condylomatous type.

In the cases I have seen surface relapse has occurred between 59 and 200 days after treatment, with an average of 83 days.

(b) *Serological relapse*: In successfully treated cases of early syphilis, positive serum tests reverse to negative in two to five months. Serological relapse is diagnosed when serial quantitative serum tests show an increasing titre of positivity following a phase of negativity or declining positivity.

(c) *Sero-resistance*: This state is diagnosed at the end of an arbitrary period of six months in cases where serial tests have shown a maintained level of positivity. In some cases there is no decline after treatment; in others there is a decline to a lower maintained level.

(d) The less common phenomena of treatment failure include neuro-recurrence, ocular and osseous relapse, and persistence of *Sp. pallida* in surface lesions in spite of treatment.

Combined treatment.—I was soon dissatisfied with the results in early syphilis treated with 2,400,000 units penicillin alone, as the early infectious relapse rate was much higher than that seen with the "20 day" arsenoxide and bismuth treatment. In planning a more

The lines of investigation of treatment methods must now, with the return of men to civil life, be turned even more towards a search for a method suitable for ambulant patients. The solution may be found in the use of vastly increased doses of penicillin in aqueous solution as already explored by Lourie (1945), or in the use of retarding substances. It has already been shown that gonorrhœa can be cured by very large doses of penicillin by mouth, and this route may be found also to have its uses in syphilis.

The long-term method of treatment of syphilis is now considered almost with contempt by some venereologists because of the impossibility of making all patients continue regularly under treatment; and penicillin is hailed because a rapid and complete treatment is possible. However, the patient treated inadequately by the old system was often a danger only to himself, whereas the patient who is not cured by a single inadequate penicillin treatment and who develops cutaneous relapse lesions is a danger to the community.

Experience has usually caused these rapid attempts to cure syphilis to become lengthened when the first flush of enthusiasm was spent. Penicillin may be the exception, but it is too soon to say.

The Anglo-Saxons have always been more optimistic about the prognosis of syphilis than have the French. Even now, knowing something of penicillin, Professor Gougerot (1945), with forty years' experience behind him, dictates that the life of a syphilitic should be divided into five periods; (1) a treatment of attack (with the most potent remedies available, lasting several months); (2) a treatment of consolidation (with bismuth, mercury, &c., lasting two to three years); (3) a period of observation and tests of cure; (4) a treatment of assurance against the disease (ten to fifteen years); and (5) a period of observation which lasts all the rest of the patient's life. Touraine (1945), another of the elders in French venereology, says of penicillin, "we still do not know if the results are of a superficial nature (he uses the excellent expression, *blanchiment*) or if it is a cure", and his advice (in a general way) is to treat intensively at the start and to prolong treatment in courses, taking no account of apparently rapid early superficial success.

I think we all agree that some comparatively rapid method of treatment is necessary to combat the lack of enthusiasm of the patient for repeated visits to hospital. Whether this can be found in penicillin alone, in single or repeated courses, or in some method of combined therapy, is a problem which, I fear, will not be settled for some time to come.

Dr. F. R. Selbie recounted some of the results he had obtained at the Bland-Sutton Institute of Pathology, Middlesex Hospital, on the effects of penicillin and penicillin combined with arsenicals in experimental rabbit syphilis. At first, an attempt was made to see whether a short course of penicillin would be as effective as a single dose of an arsenical and secondly the dosage required when penicillin was combined with arsenic in treatment was studied. On the whole he considered his results had been disappointing partly owing to the variability of the disease produced but they showed that penicillin had a rapid and dramatic therapeutic effect comparable to that of the arsenicals. This effect, however, was not as lasting as the effects obtained with the arsenicals and he thought that if, in clinical practice, penicillin was combined with arsenical drugs those latter should not be cut down to less than half the usual dose or perhaps even to two-thirds.

Mr. A. J. King: In some ways it was a misfortune that penicillin was found to be effective in the treatment of syphilis while a major war was in progress. A preparation apparently more effective than the organic arsenicals, though practically free from toxic effects, was perhaps the long-awaited ideal; but obviously to assess it for the treatment of a disease like syphilis required time, care and restraint. In the event, the pressure of circumstances was such that penicillin was introduced as the routine unsupported treatment of early syphilis in the United States Army in June 1944 and in the British Army in October 1944. The remedy was untried, and to use it as a routine under the conditions of movement

penicillin in single daily doses of from 300,000 to 500,000 units by intravenous or intramuscular route to a total of from 2,400,000 to 5,000,000 units.

LATE SYPHILIS

Osseo-cutaneous late syphilis of the acquired or congenital type reacts rapidly to penicillin in most cases, and I have had good clinical results with gummata of the testicles. Interstitial keratitis reacts equivocally to penicillin as it does to other remedies. I have treated two cases of aortitis and one of aneurysm of the femoral artery with penicillin. They were not prepared in any way beforehand, but in the first forty-eight hours individual doses were of only 10,000 units. There was no evidence of therapeutic shock. Penicillin is not spectacularly successful in producing reversal of positive serological tests in cases where the arsenicals have failed in this object.

Penicillin given by parenteral injection in the standard doses does not penetrate to the cerebrospinal fluid in demonstrable quantity, but clinical effects are manifested in spite of this. Only when very large doses are given, such as those used by Lourie (1945), is there demonstrable any penetration into the cerebrospinal fluid. The introduction of penicillin into the cerebrospinal fluid by cisternal puncture as used by Neymann and others (1945) in cases of general paralysis of the insane appears to be a hazardous proceeding. They report two deaths from chronic penicillin encephalopathy.

Clinical improvement has been reported in varying percentages of cases at all stages and in all types of neurosyphilis. Nelson and Duncan (1945) have reported on early syphilitic meningitis; Gammon, Stokes and co-workers (1945) on all varieties of neurosyphilis. The latter authors again draw attention to the rapid changes obtained in abnormal cerebrospinal fluids. These improvements, most marked with regard to cells and protein, begin in a few days and continue up to four months after which no change can be expected. The doses they used varied from 1,200,000 to 4,000,000 units and the larger the dose, the better the result. Increasing the time of treatment as well as the dose improved results and the best results of all were obtained in cases where two courses were given. They suggest giving penicillin in courses, and it will have to be determined whether the courses should be closely approximated or whether the second course should be given at the end of four months when all effects of the first will have finished.

My own observations in small numbers of cases of neurosyphilis of all types confirm the observations I have just quoted. I also have treated neurosyphilis with two courses of penicillin, each of 2,400,000 units, at a week's interval and had good results (1945). The idea was suggested to me by Professor J. W. Bigger.

In the treatment of late syphilis of all types I now begin with a course of 4,000,000 units penicillin in 100 injections of 40,000 units over twelve and a half days. This may be varied a little at the start by reduction of individual doses if therapeutic shock is to be feared. After this I give a treatment of consolidation with bismuth or with bismuth and an arsenical, depending on the type of case, and lasting at least six months.

CONGENITAL SYPHILIS: PREVENTION AND TREATMENT

Lenz, Ingraham and co-workers (1944) have reported that penicillin has good effects on mother and child in syphilis during pregnancy. Miscarriage, stillbirth, and neonatal death can be averted, and infants are born apparently healthy. Platou, Hill and co-workers (1945) report good results in infantile congenital syphilis with doses of from 16,000 to 32,000 units per kilo distributed over seven and a half days.

I have personally treated no infants and only a few pregnant women. For these latter cases I have used penicillin plus a standard course of neocarsphenamine and bismuth. Only one has so far come to term and she had a healthy child.

SUMMARY AND CONCLUSIONS

Although penicillin has been shown to be an effective agent in the treatment of all stages of syphilis, judgment of its place in the general scheme must be deferred until the cases first treated have been followed for at least five years.

There is some reason to believe that the failure rate in early syphilis is inversely proportional to the dose of penicillin so that better results may be attained when larger doses are used. Possibly giving penicillin in courses may be found better than a single treatment.

Combined penicillin and arsenical therapy gives promising results and perhaps combinations with other anti-syphilitic remedies may also be effective. I have not used penicillin and bismuth alone in any scheme of rapid treatment lasting only a week or two. This was considered but abandoned after consultation with Professor Levaditi, who could not foresee any possibility of success with such a short course of bismuth.

This assessment includes all patients irrespective of the adequacy of treatment, but the basis of comparison is probably a fair one, although practically all the patients treated with penicillin must have completed their treatment satisfactorily. Irregularity of treatment and drug intolerance are hazards which are inherent in the long-term methods of treatment of syphilis, and must be accepted as such in any comparison with a treatment which is of short duration and devoid of toxic effects.

As far as the evidence goes, and that is not very far, it appears that the anticipated results from penicillin therapy, based on the few studies available, are at any rate not far short of those obtained with standard methods. For treatment which occupies little more than a week, and carries no mortality and no unpleasant effects, this cannot be regarded as failure.

Clearly most of this comparison is speculative and is scarcely justified by the present state of our knowledge. Many concurrent investigations, of the kind which Marshall has outlined, are required, with the most accurate and complete follow-up which can be obtained. An immense amount of vital information must now be available in the War Office Central Syphilis Register, and it is disappointing that the figures quoted from this source amount to no more than 270 cases. Presumably there are difficulties because of the rapidity with which men are returning to civil life, and the fact that clerical staffs are being reduced. It seems to me that there is a good case for setting up an organisation which will follow these men by letter into civil life, and do everything possible, by co-operation with the public clinics, to obtain information as to their clinical condition and serum reactions during the next few years. My own experience from a recent follow-up of patients, treated by hyperthermy for gonococcal and other forms of arthritis, and traced in civil life, is that these inquiries are seldom resented. Most patients are anxious to help and appreciate the interest which is taken. The time for such an investigation is now; the longer it is left the more difficult it will become. With a view to this meeting I went through the case cards of patients attending the Whitechapel Clinic who had received penicillin for syphilis. The result was most unsatisfactory. There were very few from the Forces—10 out of 33 male patients—and it seems as if the instructions which these men have received to continue their tests in civil life are being disregarded. The few civilians who had received this treatment were even less satisfactory from the statistical point of view. All had received injections of arsenic and bismuth in addition, and the amounts varied greatly.

As matters stand results of treatment with penicillin alone, in so far as they are known to us, are certainly not good enough for us to be satisfied with them; and Marshall has done well to initiate experiments which may help to lower the incidence of relapsing infection. His results obtained by combining penicillin therapy with forms of intensive arsenotherapy are interesting, especially when taken in conjunction with the experiments in animals which Dr. Selbie has described. His use of arsenicals is based upon modifications of the scheme of intensive treatment by which daily injections were given for approximately twenty days. It is well to remember that this form of treatment requires the highest standards of observation and nursing care. It was said by Moore (1943) to carry a mortality of 1 in 400 cases, although Pillsbury and his colleagues, who treated over 3,000 patients by this method, had no deaths. Marshall had no deaths in his present series of 360 cases, but his one case of arsenical encephalopathy was in serious danger because the mortality in this condition is 50%.

There are certain aspects of the value of penicillin which it is legitimate to stress even at this stage of inexperience. The importance of such a therapeutic measure for defaulting and unco-operative patients in civil life, and for those who do not tolerate arsenicals or bismuth or both, is obvious. The view has been expressed that the majority of early syphilitics will get well even with treatment which is generally regarded as inadequate; but a proportion will be difficult to cure even with full and adequate treatment, for immunity processes play a large part in the cure of syphilis as of other diseases—a point which seems obvious but is apt to be overlooked. It may be that when the optimum dosage of penicillin is known it will throw into sharp relief these resisting cases, which may thus be identified early in the course of the disease and treated by one of the more radical means at our disposal, such as intensive arsenotherapy or artificial fever.

To summarize, therefore, the anti-spirochætal effect of penicillin is not in doubt; but we are far from having assessed its true and ultimate place in the treatment of syphilis. Such an assessment is dependent upon the lapse of time and also upon planned investigations which seem to have been neglected in this country. Only one system of dosage has been applied in early syphilis on a scale which should yield valuable results, and the figures mentioned in this Discussion show that assessment is being left to the unaided

which then prevailed was something of a gamble. Whether the risk was justified awaits the test of time, but preliminary impressions, based on personal experience and the few reports available, suggest that success for so short and safe a treatment exceeded the expectations of all but the most sanguine.

At the same time the conditions were laid for a large and important experiment in which many hundreds of patients with early syphilis, from a controlled and disciplined group, were treated with standard dosage of a new remedy, with facilities for follow-up and observation which would never be available in civil life. It seemed that this should provide the means for a short cut to knowledge which otherwise would take years to acquire.

In the treatment of early syphilis with penicillin alone the only studies on a scale large enough to be significant are those in which the dosage of 2,400,000 units has been given in the seven and a half day period. In Marshall's series of 67 cases followed for six months, failures of treatment amounted to 15%, of which 12% were clinical or serological relapses. The experience at the Military Hospital, Preston, was similar, showing in 105 cases 15% of failures, of which 13% were clinical relapses. Pillsbury (1944) reviewed 5,000 to 8,000 cases treated in the United States Army finding 1 to 2% of known relapses in patients observed for one to ten months after treatment. In 792 of his cases the blood serum was tested six months or more after treatment and 13% had positive Kahn tests. There is no evidence as to how many of these were serological relapses and in how many the serum reactions failed to respond. This appears to be an almost identical proportion of failures, with the difference that in the British cases the percentage of actual clinical relapses was much higher. In early syphilis under treatment the persistence or relapse of positive serum reactions is so strong a pointer to the probability of clinical recurrence that this difference would not seem to be significant. The remaining evidence on this point comes from the War Office study of 270 cases treated with penicillin and followed for six months, in which the relapse rate was 8%, and from Dr. Earle Moore's personal communication to Colonel Marshall, from which it seems that relapse rate in a large series of cases followed for eight months was 7%. It is presumed that in these series the term "relapse" is intended to include clinical and serological relapses and also those cases in which the serum reactions did not respond.

If Marshall's figure of 12% of relapses in the first six months after treatment is considered in relation to the observation of the Co-operative Clinical Group in the United States, based on a large number of cases treated with standard courses of arsenicals and bismuth, that 45% of relapses of all kinds occurred within six months of the completion of treatment, it is possible to estimate that the number of relapses to be anticipated in the final assessment of Marshall's series is 29%. To this figure must be added the 2% of his cases which were sero-resistant, for the extent of this type of failure is obvious within the first six months. Thus the total proportion of estimated failures in his cases would be 31%. This may well be an overestimate if there is a close analogy between the effects of the organic arsenicals and penicillin, both of which are quickly acting remedies, quickly absorbed and quickly excreted. There is evidence that the organic arsenicals, when given alone in inadequate dosage, may shorten the latent period of relapse; it is believed that in cases treated with intensive arsenotherapy the majority of relapses occur within six months and almost all occur within the year. It is reasonable to suppose that the cycle of relapse and progression may also be hastened by penicillin.

In order to assess the significance of these estimated figures it is of interest to compare them with statistical studies relating to the long-term treatment of early syphilis with arsenic and heavy metal. The most comprehensive of these studies is that of the Co-operative Clinical Group from the publications of which (Stokes *et al.*, 1932) the following table is adapted:

EVIDENCE OF RELAPSE AND RESISTANCE TO TREATMENT IN 3,244 CASES.
(CO-OPERATIVE CLINICAL GROUP.)
(The Figures are Percentages.)

Results of treatment	Sero-negative primary	Sero-positive primary	Early secondary
Relapse, serological... ..	6.4	0.0	10.7
Relapse, clinical... ..	2.6	2.7	2.0
Neuro-relapse, clinical or serological... ..	1.8	3.0	4.4
C.S.F. persistently abnormal... ..	.6	1.0	1.3
Positive blood W.R. irreversible for 1 year or less... ..	1.2	7.5	5.5
Positive blood W.R. irreversible over 1 year... ..	2.6	7.0	7.8
Totals... ..	15.2	32.0	32.6

Average of failure in 3 groups = 20.6 %.

date. All cases described have been primarily diagnosed by the finding of the *Sp. pallida*. Out of a total of 370 cases of primary and secondary syphilis, 295 cases are available for evaluation purposes—the 75 cases not included, being all of less than one month's surveillance. Of the 295 cases, there were 105 with a surveillance period of from one month to four months inclusive (77 of these cases are already negative) and 190 cases from five months to seventeen months. We had 6 relapses in 223 primary cases, and 12 relapses in 72 secondary cases, a total of 18 relapses in 295 cases, or roughly 6%. This arbitrary period of four months was taken as all our cases are kept in their home depot for surveillance for this length of time prior to being drafted. Whether by the I.V. or I.M. method the conclusions arrived at, based on the results of our work point to the fact that, with a total dosage of less than 3.9 M.U. in primary syphilis, and a total dosage of less than 4.8 M.U. in secondary syphilis—relapses will occur. With the doses now considered to be minimal, i.e. 13 daily injections of 300,000 units or 8 daily injections of 500,000 units for primary syphilis, and 16 daily injections of 300,000 units, or 10 daily injections of 500,000 units for secondary syphilis, there have been no relapses to date.

Miss G. M. Sandes: I have used penicillin in the treatment of congenital syphilis but do not advise it in every case. Congenital syphilitics under the age of 10 years may be grouped as: (1) The florid types. These in my experience do well, but it is advisable not to give penicillin to the infant when it is first admitted acutely ill. When we did this we found that there was an acute exacerbation of symptoms, especially catarrhal, and that these infants tended to be "drowned in their own secretions". For this reason we now defer giving the penicillin until ten to fourteen days later, when three or four doses of intramuscular acetylarsan for children will have been given. Penicillin is then administered by 20,000 units intramuscularly, three-hourly dose day and night (omitting one dose at night because of sleep) until a total of half a million units have been given. This was the procedure if the infant was under a year. From 1 year to 5 years old, a child received a total of 750,000 units of penicillin.

(2) Milder types with few signs but with a positive blood Wassermann reaction. I do not consider that I can adequately assess the value of this treatment in these milder cases.

(3) Congenital syphilitics with bone affections respond rapidly to treatment with penicillin. Radiologically the lesion "melts away" but arsenic and mercury or bismuth therapy must be continued subsequently for some time, in the present state of our knowledge.

Finally, there are some cases which have caused me great anxiety, namely, women married to men who had been assured that the treatment with penicillin alone which they had received in the Forces had been sufficient to effect a cure. When pregnant the woman's blood Wassermann reaction was strongly positive in each case. Intensive treatment to the mother produced one congenital syphilitic baby but the other two mothers fortunately were delivered of healthy children.

I should like to ask Dr. Marshall about the condition of the cerebrospinal fluid in those patients which he mentioned where the blood Wassermann reaction remained persistently positive.

Colonel L. W. Harrison supported Brigadier Osmond's view that the analogy with "606" was a strong one. He would remind them that the results obtained by the workers at the Military Hospital, Rochester Row, and by Gennerich at Kiel between 1910 and 1914 showed that with less than three months' steady treatment with an arsphenamine preparation and heavy metal one could achieve a very high percentage of cure, approaching that obtained with the year's treatment that was routine to-day; the additional courses after the first might be likened to the disproportionate amount of fuel required to squeeze out extra knots in a ship's speed after attainment of the optimum. He described investigations on substances which retarded absorption of penicillin, in which 24 centres had collaborated with him. He had used suspensions in arachis oil containing 2, 2.5, 3.2, and 3.5% beeswax, and in ethyl oleate containing 4, 5, 6, and 7% beeswax. These had been in a concentration of 50,000 units per c.c., but he had also used stronger concentrations of penicillin in ethyl oleate with 4% and 5% wax. Generally, in agreement with Kirby *et al.*, there had not been a very significant difference in the proportions of penicillin he had found in blood serum and urine after injection of these suspensions, but he had thought that 3.5% wax in arachis oil was better than 2.5% and that 6% wax in ethyl oleate was at least as good as 3.5%

enterprise of individuals, rather than planned on the national scale, which the size of the problem and the nature of the material demand. As far as present investigations go they indicate that the system of treatment which has been used may be expected to produce a proportion of successful results similar to those obtained with standard long-term treatment with arsenic and heavy metal, even though the hazards of irregularity and toxicity are removed. The urgent need is to take steps to assess by means of follow-up the large number of cases which has been treated in the Services during the past eighteen months. On the basis of this knowledge other schemes of treatment can be planned. The possibility of synergistic action between arsenicals and penicillin is at present no more than an idea, though the place of combined treatment for syphilis requires investigation, as do many other problems. The urgent need of the moment is to explore and exploit to the full the outstanding virtues of penicillin itself, namely its speed, its immediate efficiency and its apparent lack of toxicity.

Brigadier T. E. Osmond thought the papers were most valuable particularly in view of the wide experience of their authors: he would have preferred the subject to be entitled "The Place of Penicillin in the Treatment of Syphilis" because penicillin alone would not cure all cases. He compared penicillin with arsenic in that both tended to fail to live up to the early hopes reposed in them, and with both, bigger and bigger dosage was used.

Results obtained in the American Army were much better than those in the British—there appeared to be no explanation of this. Relapse and reinfection were difficult to distinguish; the latter should always be suspect; the causes of the former might be several—the spirochate being encysted in avascular tissue, or it might have a resistant stage in its life cycle or there might be "persisters" as suggested by Professor Bigger. He did not know whether penicillin should be given in long or short-repeated courses or supplemented with arsenic or bismuth, or both, but he thought that bismuth had been rather overlooked in favour of arsenic; both penicillin and arsenic were excreted rapidly whereas bismuth remained in the tissues over long periods.

To estimate the effect of treatment, one needed a good quantitative test and a central laboratory should guide such testing.

He thought penicillin a wonderful remedy, but it should be subjected to controlled investigation and not used haphazard.

Surgeon Captain T. R. Lloyd-Jones, R.N.: It has been our aim at "Navy Wing", Cosham, since August 1944, to evolve an efficient scheme of treatment which could be used on ambulatory patients. Earle Moore has put forward certain schedules of treatment, some with penicillin alone, others combined with different doses of arsenic, &c., to be carried out by different groups. We chose to carry out our investigations with penicillin alone, and also decided to base our work on the single daily injection method.

Our first experiments were to find out what single minimal dose would remove *Sp. pallida* from surface lesions and would ensure that they would still be absent over a period of twenty-four hours. Doses below 160,000 units were found to be inconsistent in this respect, but with this dosage the *Sp. pallida* disappeared in an average of eleven hours and remained absent at twenty-four hours. We took as our starting point the standard dosage of 2.4 mega units spread over seven and a half days as used in the U.S.A., but the 160,000 unit dose daily would have required a period of fifteen days. In order to adjust the time dose relationship we stepped up our daily dose to 300,000 units entailing eight days' treatment. At the commencement of our work the intravenous method was adopted and as experience and results were obtained the total dosage had to be increased according to the stage of infection, as relapses had occurred. The results of the work done by the intravenous method were most encouraging but in view of the simplicity of administration by the intramuscular route, with the probable elimination of any tendency to therapeutic shock, the intravenous method was discarded in favour of the intramuscular method in March 1945, and this method has been in use since that

Section of Dermatology

President—SYDNEY THOMSON, M.D.

[January 17, 1946]

DISCUSSION ON PHOTOGRAPHY IN RELATION TO DERMATOLOGY

Dr. A. C. Roxburgh: My objects in suggesting to the Council of the Section that this meeting should be devoted to photography in relation to dermatology, were three in number.

First, to encourage the members of the Section to use photography more for recording their interesting cases for publication, or their typical ones for teaching purposes.

Secondly, to show that it is easy to take quite passable and useful photographs with quite simple apparatus.

Thirdly, to show what can be done by experts in the way of representing skin diseases by photography, either in black and white or in colour, in prints and transparencies.

For record and teaching purposes I find ordinary black and white glossy half-plate prints the most convenient, for it is easy and cheap to make as many copies as desired. For record, they can be put in with the patient's notes, and for teaching they are handed round the class who can study and compare them at leisure. Really good colour prints would be better still, but they are very expensive. In many the colours are inaccurate and the detail indistinct. Transparencies, though better than most colour prints, are much more difficult to demonstrate as they require a darkened room.

The camera I use is an ordinary Rolleiflex twin-lens reflex taking 12 pictures, each $2\frac{1}{4}$ in. by $2\frac{1}{4}$ in., on the ordinary size 20 Selochrome film. I use a wire cable release to avoid shaking the camera; a lens hood to keep glare off the lens and two Proxar lenses for close-up work. For light, I use two "Photofloods" in holders with white reflecting surfaces, one as a main light and the other, farther away, to light the shadows. A dark screen makes a good background. A Weston electric exposure meter is a great help but I find that nearly all my photographs are taken at a fifth to a tenth of a second at f 5.6 to f 6.3. A notebook for recording patients' names and ages and details of the case, lighting, and exposure, is essential.

It is important to use ortho- and not pan-chromatic film as pan-film renders reds too light and not sufficiently in contrast with the normal skin. I always develop and enlarge my photographs myself as I find that only in that way can I get the prints to show the particular details required.

Squadron Leader H. Mandiwall: The ordinary technique in black and white photography applies equally to colour. The only difference is that the negative used instead of being ortho- material is Kodachrome. All my work in the past has been done with a Leica 35 mm. camera with Kodachrome film.

in arachis oil. After an injection of 300,000 units in oil-wax one could usually reckon on finding penicillin in the blood serum for twelve to sixteen hours, but he had not found it often in the serum at the end of twenty-four hours. On the other hand he had commonly found it in the urine seventy-two hours after such an injection, and sometimes at the end of ninety-six hours. He thought that the finding of Kirby *et al.*, that there was a longer hold-up after subcutaneous than after intramuscular injection, was important, and it seemed to him likely that the deep subcutaneous route would prove preferable to others. There was no clear evidence to show how much or for how long an assayable amount of penicillin must remain in the blood. He thought that Kirby's results in early syphilis after giving a daily dose of 300,000 units in oil-wax for eight days indicated that it was not necessary that an assayable amount of penicillin should remain in the blood throughout the period over which the penicillin treatment of syphilis was spread, and he had hitherto recommended clinics using the oil-wax suspensions to give a daily injection of 300,000 units for eight days, as the penicillin contribution to the treatment of syphilis. In a recent circular, however, he had suggested that, if practicable, two injections of 300,000 a day for five days might prove to be a more efficient course.

The strength of penicillin in the suspensions which he had tested hitherto had mostly been only 50,000 units per c.c., because of the relatively low potency of the product. Purer penicillin was shortly to become available and the investigation was to be continued with suspensions containing 100,000 or more units per c.c. Theoretically, the tighter the penicillin was packed into the dose, the slower should be the absorption; on the other hand one had to see that the viscosity was not such as to make administration too difficult and waste of the suspension through adhesion to the vial unduly great. He would express his indebtedness to his collaborators. His part in the work had been to devise the suspensions and do the tests for penicillin on which he had commented. Some collaborators had reported brilliant clinical results following the course of eight daily injections of 300,000 units.

Dr. J. Marshall (in reply to Miss Sandes): In the British Army the surveillance tests after any rapid treatment (whether by penicillin, arsenic or both) include an examination of the cerebrospinal fluid six months after completion of treatment. Lumbar puncture was also performed as a routine in any case of relapse seen in my hospital. Some hundreds of such tests have been performed and I have not as yet encountered any case in either group in which abnormalities in the cerebrospinal fluid were demonstrable.

Lighting is artificial by means of two or more "Photoflood" electric light bulbs. When using artificial light for colour film the illumination must not be mixed, as a mixture of daylight or ordinary electric light with "Photoflood" will spoil the colours entirely. For colour flat lighting is best; occasionally in black and white work oblique illumination may bring out some particular detail better.

Exposure times (using an $f\ 3.5$ aperture) are $1/30$ th second for colour, using Kodachrome A film, and $1/40$ th to $1/60$ th second for black and white panchromatic film. Alternatively you may, instead of reducing your exposure time for black and white film, close down your lens aperture slightly instead. Many of your patients will not keep still, and therefore you must use as fast an exposure as possible. It is impossible to get a good picture of any kind, say of an unruly infant with scabies, with an exposure of $1/5$ th second! For close-up work (between 2 feet and 6 inches) I use a "Nooky" close focusing device which is a coupled focusing attachment which corrects simultaneously for parallax. Parallax errors are liable to occur when taking close-ups due to the fact that you see the object through one aperture (the view-finder) and the camera takes the picture through another in a different plane (the lens). It is liable to be very marked indeed when taking at distances under 18 inches, and you may find that you have completely missed your particular target if you do not compensate for parallax. In the Reflex Kōrelle camera there is no need to compensate for it, as it uses the same lens aperture for both viewing and taking the subject.

The background used in taking colour photographs of the skin in its true tint is very important. I have found that a blue-coloured one is very effective, possibly because blue is complementary to red.

Photomicrographs in colour require no expensive equipment, only a camera, an ordinary microscope and one "Photoflood" electric light bulb (*see Proc. Roy. Soc. Med.*, 1942, 35, 700). The method is as follows:

The section is placed and focused under the microscope in the ordinary way (this must be done by a normal emmetropic eye, and if you have to wear glasses yourself you must get someone else with normal vision to do this), then the microscope with the slide in position is tilted into the horizontal position and the reflector adjusted to give good illumination. The miniature camera is brought up to the ocular of the microscope in the same horizontal plane until it just touches it firmly. All extraneous light is excluded by means of some suitable covering, e.g. a piece of dark cloth wrapped round the junction. Film used is Kodachrome A (for artificial light). One "Photoflood" light is used and reflected as described above, instead of any other source of illumination. Camera lens is set for infinity, aperture $f\ 3.5$ and exposure $1/5$ th second.

I have constructed a home-made apparatus for clinical work which carries the Leica, or other camera, in the centre, together with the necessary illuminating outfit, which can be moved about in any direction. This has been in use by me for several years, both in hospital and private work.

[Black and white and coloured dermatological photographs and photomicrographs were then shown.]

Mr. P. G. Hennell: My experience of colour photography covers approximately twelve years, using all the proprietary processes. As a professional photographer I am biased against 35 mm. equipment, although it has certain advantages for working in confined spaces. For quality I think the largest camera possible should be used.

The first slide showed a diagram of the internal construction of a colour camera originally invented in Germany and now manufactured in America. The $\frac{1}{4}$ plate negatives used allow enlargements up to 20 in. by 30 in., without loss of register. The next slide showed the Speed Graphic Camera, which I recommend for use with Dufay and Kodachrome colour film. The complete outfit contains a synchronized magnesium flash gun, and the latest model is fitted with a plastic lens, the definition of which is finer than that of any lens I have used hitherto.

Using the one-shot colour camera I light the subject with a magnesium flash gun, consisting of a sashalite pistol grip containing 4 U2 batteries with a 16 in. reflector, which takes up to 5 large sashalite bulbs, wired to ignite simultaneously. The acetate screen on the front contains the blue filter which corrects the light of the flash bulbs to daylight, for which the colour camera is balanced.

This equipment was ideal in Italy as I was able to work independently of any electrical installation. Another type of lighting worthy of serious consideration by those establish-

The technique is very simple and an ordinary amateur can record cases in colour without sending the work to outside photographers. It is advantageous to have a camera at hand to record your cases, treatment and results at various intervals. In spite of the very good black and white photographs which we have seen published in books and magazines, I think that colour photography brings out more detail and gives more realistic clinical pictures. The skin lesions have a colour of their own and so why not record them as such; besides a colour photograph, especially from the teaching point of view, impresses the mind to a very great extent.

[Colour slides were then shown.]

A meter to determine the exposure is very important in colour work and once you have standardized exposures, by copying a coloured chart, you know your results will be correct at all times.

Mr. J. E. Andrews, A.R.P.S., *Medical photographer, London County Council*: When a doctor at any one of the London County Council hospitals is desirous of having photographic work done he simply sends a request form to the central photographic laboratory. The medical photographer then goes along to the hospital to do the work required. I think one really well-equipped photographic laboratory can maintain an efficient service to several hospitals. All photographs are the copyright of the London County Council.

I have found that a half-plate camera with at least four lenses having focal lengths of 12 in., 8½ in., 6½ in., and 4¾ in., comes very near to perfection for most branches of medical photography, particularly in my own case where most of the work is done at the bedside and not in a room set aside for photography.

The camera is clamped to the top of a pair of steps about 6 ft. 6 in. high enabling the camera to be brought over the patient lying in bed. A "Photoflood" lamp with 6 feet of flex, plugs in to the existing light fitting over the bed. By interchanging the lenses I can photograph full-length figures or close-ups. I prefer to use cut film because it is lighter than glass plates and there is no risk of breakage. About 70% of my pictures are taken on a medium-speed orthochromatic emulsion.

The difficulty of photographing very small fields and cavities led me to devise the arrangement of a ¼ plate camera mounted on a board with the lens extended and fixed at a point, so that all objects at the opposite end of the board were sharply defined on the plate. The lens is stopped down to f 6.4, in order to produce great depth of focus. The lighting is by a flash bulb fixed just behind the lens and in line with the optical axis. With this unit I can get thoroughly sharp pictures of the inside of the mouth or similar subjects, because, if the patient moves, the entire unit is moved with him.

[Lantern slides of patients photographed by the bedside method and the fixed focus camera described, were shown.]

Dr. F. A. E. Silcock: My own methods of doing clinical dermatological photography are based on many years of practical work in black and white and of seven years of colour photography.

I use a Leica camera with coupled range-finder and focusing device for 35 mm., and a Reflex Korelle for 2¼ in. sq. pictures. Both can be used for black and white, but the former only for artificial light work (Kodachrome A film) and the latter for Dufaycolour. I prefer Kodachrome film for colour. The Reflex Korelle is a single lens reflex type camera in which there is a single lens, through which one both views and takes the picture, a mirror being set at an angle of 45 degrees (which reflects the picture), and this swings out of the way at the moment of exposure. You thus see exactly what you are going to take.

It is essential to have a good lens and I use an aperture of f 3.5. This allows for fast work and good depth of focus. For close-up work anything, say, from a distance of 2 feet to 6 inches away, it is necessary to use either supplementary lenses or an extension tube, both being methods of decreasing the focal length. Against using supplementary lenses is the fact that you require a number of them and they will only work at their fixed focal distances. This is a great drawback in taking a moving object whose distance is changing rapidly. I therefore prefer an extension tube. This is a short length of metal tubing, about half an inch in length, which is inserted between the lens and the body of the camera. Its use does not necessitate any increase in exposure time as supplementary lenses do.

Lighting is artificial by means of two or more "Photoflood" electric light bulbs. When using artificial light for colour film the illumination must not be mixed, as a mixture of daylight or ordinary electric light with "Photoflood" will spoil the colours entirely. For colour flat lighting is best; occasionally in black and white work oblique illumination may bring out some particular detail better.

Exposure times (using an $f\ 3.5$ aperture) are $1/30$ th second for colour, using Kodachrome A film, and $1/40$ th to $1/60$ th second for black and white panchromatic film. Alternatively you may, instead of reducing your exposure time for black and white film, close down your lens aperture slightly instead. Many of your patients will not keep still, and therefore you must use as fast an exposure as possible. It is impossible to get a good picture of any kind, say of an unruly infant with scabies, with an exposure of $1/5$ th second! For close-up work (between 2 feet and 6 inches) I use a "Nooky" close focusing device which is a coupled focusing attachment which corrects simultaneously for parallax. Parallax errors are liable to occur when taking close-ups due to the fact that you see the object through one aperture (the view-finder) and the camera takes the picture through another in a different plane (the lens). It is liable to be very marked indeed when taking at distances under 18 inches, and you may find that you have completely missed your particular target if you do not compensate for parallax. In the Reflex Kōrelle camera there is no need to compensate for it, as it uses the same lens aperture for both viewing and taking the subject.

The background used in taking colour photographs of the skin in its true tint is very important. I have found that a blue-coloured one is very effective, possibly because blue is complementary to red.

Photomicrographs in colour require no expensive equipment, only a camera, an ordinary microscope and one "Photoflood" electric light bulb (*see Proc. Roy. Soc. Med.*, 1942, 35, 700). The method is as follows:

The section is placed and focused under the microscope in the ordinary way (this must be done by a normal emmetropic eye, and if you have to wear glasses yourself you must get someone else with normal vision to do this), then the microscope with the slide in position is tilted into the horizontal position and the reflector adjusted to give good illumination. The miniature camera is brought up to the ocular of the microscope in the same horizontal plane until it just touches it firmly. All extraneous light is excluded by means of some suitable covering, e.g. a piece of dark cloth wrapped round the junction. Film used is Kodachrome A (for artificial light). One "Photoflood" light is used and reflected as described above, instead of any other source of illumination. Camera lens is set for infinity, aperture $f\ 3.5$ and exposure $1/5$ th second.

I have constructed a home-made apparatus for clinical work which carries the Leica, or other camera, in the centre, together with the necessary illuminating outfit, which can be moved about in any direction. This has been in use by me for several years, both in hospital and private work.

[Black and white and coloured dermatological photographs and photomicrographs were then shown.]

Mr. P. G. Hennell: My experience of colour photography covers approximately twelve years, using all the proprietary processes. As a professional photographer I am biased against 35 mm. equipment, although it has certain advantages for working in confined spaces. For quality I think the largest camera possible should be used.

The first slide showed a diagram of the internal construction of a colour camera originally invented in Germany and now manufactured in America. The $\frac{1}{4}$ plate negatives used allow enlargements up to 20 in. by 30 in., without loss of register. The next slide showed the Speed Graphic Camera, which I recommend for use with Dufay and Kodachrome colour film. The complete outfit contains a synchronized magnesium flash gun, and the latest model is fitted with a plastic lens, the definition of which is finer than that of any lens I have used hitherto.

Using the one-shot colour camera I light the subject with a magnesium flash gun, consisting of a sashalite pistol grip containing 4 U2 batteries with a 16 in. reflector, which takes up to 5 large sashalite bulbs, wired to ignite simultaneously. The acetate screen on the front contains the blue filter which corrects the light of the flash bulbs to daylight, for which the colour camera is balanced.

This equipment was ideal in Italy as I was able to work independently of any electrical installation. Another type of lighting worthy of serious consideration by those establish-

ing clinical photographic units is the "Kodatron" type of gaseous discharge lamp. With this lamp one can fire upwards of 5,000 flashes without replacing the flash tube, from which the light is emitted. The effective length of the exposure is approximately a 30,000th of a second, and for this period the brilliance of the light has been estimated at approximately that of 40,000 100 watt lamps. Owing to the high speed the brilliance appears to the naked eye to be less than that of an ordinary magnesium bulb.

For photographs made in the operating theatre I prefer to use blue or green sterile drapes, these colours tending to isolate effectively the operative site to be photographed.

Other slides were shown depicting scenes in the underground air-raid shelters in Naples, where there had been a serious outbreak of typhus. These photographs were made with the Speed Graphic Camera and Kodachrome Film. There were also slides showing D.D.T. being sprayed on the civil population at the railway station.

Other slides showed examples of the new types of colour photography now being produced in America, notably amongst which were examples of the Kodacolor colour negative from which an unlimited number of prints on paper can be made.

Unfortunately, there has been a great deal of exaggeration in the textbooks in the reproduction of colour, and perhaps for many purposes the black and white photograph is still the best. However, I do think that the advantage of colour photography lies in its ability to reproduce shades too delicate to be shown in black and white. If you wish to exaggerate you can do it much more successfully in black and white than in colour, but in certain conditions accurate colour photography is the only satisfactory means of reproduction.

I understand that British firms are intending to manufacture gaseous discharge lamps, and I think the speed at which they will be available will be dictated largely by the demand.

In answer to a query regarding plastic lenses, I have not experienced any scratching; the definition is quite remarkable. I have not used another lens which gave as good a performance at the aperture of 4.7 at which the Italian shelter photographs were made. They are not readily available in this country yet, and those that are have scarcity prices attached to them. Likewise there are people who will pay £100 for a Leica or Contax camera. In my opinion there will be American cameras of equal performance for something in the region of £20 on the European market before very long.

Mr. C. H. J. Bishop: The cost of reproduction of photographs in colour in a magazine or technical journal may seem out of all proportion to the original cost of the photograph, but we have to bear in mind that the colour print has to be separated into four sections, into the three primary colours and black. The charge for the block is reckoned at so much per square inch, and an average sized block of, say, 11 in. by 7 in. costs about £30.

The block-maker can make or break one's most beautiful work—more often than not he breaks it! The reproduction is often nothing like the original, and frequently is quite useless for medical purposes. There is only one way to obviate all this, and that is close association with the block-makers. My own experience of block-makers is that unfortunately at the present time they are mostly elderly men and they are colour-blinded by their own peculiar conditions. Quite a number of printers are, to all intents and purposes, colour-blind because they are so accustomed to work under arc light that they do not know daylight when they see it.

To reproduce satisfactorily, special filters are required which the block-maker does not have and if you tell him you want narrow cut separation, he will not like it at all.

Therefore, if you are going to publish colour photographs which are to be anything like the original, you must insist that the man who does it knows what he is doing. You will certainly not reach the level of the American publications in the matter of colour reproduction until you spend more money on block-making.

Dr. F. A. E. Silcock: With regard to the comments by Mr. Bishop on coloured blocks, I think it might be done by getting reproductions of your 35 mm. or any other size prints and dealing with them like a collection of stamps. You could give them numbers and if, at a later date, a better specimen came along, remove the old picture and replace it.

Mr. Bishop: It is true we have had six years of war and our printing machinery is not what it was and certainly not what the American machinery is, but when we get going

properly and bring our machinery up to date, I am convinced we shall do as well as the Americans. Apropos of the false tints sometimes found, the Dufay Company has produced a series of filters and they will tell you what combination to use. The background is a problem which wants careful watching, otherwise you can completely ruin the picture by the choice of an unsuitable colour which may reflect on to the subject and degrade its colouring.

[February 21, 1946]

? Poikiloderma Jacobi: ? Atrophic Lichen Planus.—A. C. ROXBURGH, M.D.

P. B., male, aged 57. Patient of Dr. Sears of Lyndhurst, Hants, seen on January 9, 1946.

For twelve to fourteen years reticular arrangement of red, atrophic skin on front of forearms, from wrists to elbows (fig. 1), and over whole of feet and ankles except toes (fig. 2). No definite papules but a slight suggestion of them in shiny polygonal islands between the skin furrows on forearms. In last twelve months has from time to time had blisters at sides of each tendo Achillis, one present when seen and another, ascribed to a rubber boot, on dorsum of one foot. No lichen planus in mouth or on penis. Teeth very bad. Otherwise healthy. No symptoms except in two weeks up to January 9 "pins and needles" in both hands, lately only in right thumb and index finger.

Dr. J. E. M. Wigley: I think this is the variety of parapsoriasis described by Macleod and others as parakeratosis variegata (J. M. H. Macleod, *Diseases of the Skin*, London, 1920, p. 847).

Dr. G. B. Dowling: I have seen a small number of these cases. They seem always to have the same distribution, affecting especially the outer aspect of the forearms and ankles. The cases I have seen have been subjects over 50. The condition was described in 1926 (C. D. Freeman, *Arch. Derm. Syph.*, 1926, 13, 489) under the title of erythematous lichen planus elsewhere, and there is always the characteristic distribution on the forearms and ankles. I have thought that the condition, itself very well defined, can hardly be identified with any named dermatosis, and may be an entity.

Dr. R. T. Brain: The clinical appearances are suggestive of poikiloderma, although the distribution of the lesions is unusual.

Patchy Punctate Pigmentation.—A. C. ROXBURGH, M.D.

Recurrent attacks of patchy, scaly erythema and purpura followed by pigmentation. Case shown at British Association of Dermatology meeting July 6, 1945. No diagnosis then arrived at (Jacobi's poikiloderma and angioma serpiginosum suggested) (*Brit. J. Derm.*, 1946, 58, 26).

Miss P. L., aged 22. Clerk.

History.—(1943 Summer): Noticed brown patch right side of neck.

1944 (Summer): Fresh lesions began to appear.

1945 (July): A number of symmetrical pigmented areas 2 to 3 in. in greatest diameter, of irregular shape, smooth or slightly scaly, covered with dark brown points like hæmorrhages being absorbed, situated on front and sides of neck, over each deltoid, front and inner side of each upper thigh and on left hip. Patches on deltoid regions (only) are stated to go repeatedly through a cycle of bright red spots "like red ink" which turn purple and then leave brown marks.

1945 (December 28): Red spots appeared on neck, arms, lower abdomen. No irritation.

1946 (January 6): Felt ill. Bed. T. 100° in day, higher at night. Enlarged glands in neck. Fresh areas of eruption.

1946 (January 11): Seen. Red, scaly plaques with sharp margins, slightly crusted in places, each side of neck including angle of jaw on right, with purpuric spots near upper margin, also symmetrically on top of shoulders and covering front, back and outer sides of upper arms. Purpuric eruption, dappled, but with smooth surface front of each forearm. Purpuric dappling lower abdomen to 2 in. above pubes, also front of each thigh and over whole of both buttocks which were tender to sit upon. Slight dappling backs of knees outer sides but flexures of elbows normal. No enlarged glands.

1946 (February 5): Seen in Royal Masonic Hospital. All redness disappeared and replaced by pigmentation, punctate in places, especially on neck. Small group of crusts lower right buttock (fig. 3).

Patient takes no drugs except occasional Beecham's pills or Epsom salts. No sedormid, adalin or phenolphthalein. Eats plenty of green vegetables. Otherwise well except for frontal headaches. Menses within normal limits. Never any redness or swelling of face or eyelids.

Investigations.—Biopsy from pigmented area left buttock.

Blood and urine examinations normal. W.R. negative.

Jaw: Unruptured wisdom tooth each lower jaw, that on left impacted.

FIG. 1.

FIG. 2.

FIGS. 1 and 2.—Dr. Roxburgh's male case for diagnosis. ? Poikiloderma Jacobi: ? Atrophic lichen planus.

FIG. 3.—Dr. Roxburgh's female case for diagnosis, showing patchy pigmentation on buttocks, shoulders, upper arms and right elbow.
(Photographs by Dr. A. C. Roxburgh.)

FIG. 3.

Dr. Freudenthal: Section (Fig. 3) shows capillary vessels markedly increased in papillary body. Perivascular oedema and slight infiltration. Melanin considerably increased, especially in basal layer. No iron. The sections suggest that the case is primarily a vascular disturbance which has led to an increase in melanin production.

Reticulo-endothelioma (Spiegler-Fendt Tumour).—G. W. BAMBER, M.D., and W. FREUDENTHAL, M.D.

Dr. G. W. Bamber: Mrs. R. K., aged 80, was first seen by us in December last when she said that her scalp had started to become tender and to swell two and a quarter years previously. Examination showed the right side of the vertex, the front of the scalp and the upper half of the forehead to be the site of a large reddish infiltrated plaque the surface of which was mammillated in some parts and in others resembled peau d'orange. On the forehead the boundary between infiltrated and normal skin was a sharply defined furrow. Almost half the surface of the lesion was eroded by a large ulcer that had become infected secondarily. Clinically the lesion was thought to be a neoplasm and this supposition was confirmed by the histological examination of a biopsy. Sections showed a peculiar vascular proliferation of the type described by Spiegler and by Fendt.

Her blood Wassermann reaction was negative.

The tumour consists of larger or smaller foci of densely aggregated mesenchymal cells. In some places it has a tendency to form fissures and vascular spaces, sometimes producing vessels of considerable size whose walls display a very active proliferation of endothelial cells which form a kind of lining. We think that these fissures and vascular spaces are an irregular attempt at forming lymph vessels. We regard the tumour as one arising from lympho-reticular tissue and suggest that this case should be grouped with the Spiegler-Fendt endotheliomas though we are not aware that a histological picture quite identical with this has been recorded.

Dr. I. Muende: I agree entirely with Dr. Freudenthal in that this is an affection of the endothelial lining of the vessels, but cannot accept it as being an endothelioma in the sense that it is a tumour of the endothelial cells. In my opinion it would better be described as an endotheliosis.

Dr. W. Freudenthal: "Reticulosis" covers a wide range of proliferative dermatoses. It includes Spiegler-Fendt's endotheliomas, a term generally accepted (Spiegler, E., *Arch. Derm. Syph.*, Vienna, 1899, 50, 163; Fendt, H., *Arch. Derm. Syph.*, 1900, 53, 213). It should not be confounded with Spiegler's "turban" tumours which are basal-cell epitheliomas, occasionally of sweat gland origin.

Balanitis Xerotica Obliterans.—J. E. M. WIGLEY, M.B.

C. H. A., male, aged 41. Married. Three years' history of recurring attacks of eruption about the glans penis and inner surface of the prepuce. He describes the eruption as numerous small blisters accompanied by a varying degree of discomfort. This was treated by various methods under a diagnosis of herpes progenitalis. He saw Dr. Dowling early last year who tells me that, having excluded an infection with monilia, he was still not satisfied that the condition was herpes progenitalis. The eruption seemed too nearly continuous. A thorium-X paint, containing 500 units per c.c., was applied on two separate occasions. The patient states that there was increase of the pain and swelling within twenty-four hours of each application. He was subsequently seen by a surgeon who found a balanitis with adhesions between the prepuce and glans. Circumcision was performed in August 1945 when it was noted that the adhesions were more tough than was anticipated. The wound was unusually slow in healing. The patient complains that his glans is still sensitive and sore, the remains of the prepuce appearing to him to be closely bound to the corona and giving him great discomfort on erection. He has not noticed any changes in the volume or trajectory of the stream of urine.

On examination.—The glans presents a white, shiny, slightly atrophic irregular area. The remains of the prepuce are firmly bound to the back of the corona and along this junction there is some dark pigmentation and some telangiectasia. Otherwise there does not appear to be anything abnormal.

My first impression on seeing this case was of its close resemblance to X-ray dermatitis and I was inclined to accept the patient's story of the connexion between the application of thorium X and the present condition. The amount of thorium X used seemed much too small to have produced this effect. More careful study of the lesion showed the marked resemblance of the whitish, atrophic area to the condition described as lichen sclerosus, which has been included under the group of cases of kraurosis when occurring about the vulva (Early Kraurosis Vulvæ in a Child, J. E. M. Wigley, *Brit J. Derm.*, 1944, 56, 20).

This case is, in my opinion, one of balanitis xerotica obliterans described by Laymon and Freeman and others and given the synonym of kraurosis penis. The occasional superficial resemblance to X-ray dermatitis has been noted, as well as the histological resemblance to both lichen sclerosus and morphea.

1946 (February 5): Seen in Royal Masonic Hospital. All redness disappeared and replaced by pigmentation, punctate in places, especially on neck. Small group of crusts lower right buttock (fig. 3).

Patient takes no drugs except occasional Beecham's pills or Epsom salts. No sedormid, adalin or phenolphthalein. Eats plenty of green vegetables. Otherwise well except for frontal headaches. Menses within normal limits. Never any redness or swelling of face or eyelids.

Investigations.—Biopsy from pigmented area left buttock.

Blood and urine examinations normal. W.R. negative.

Jaw: Unerupted wisdom tooth each lower jaw, that on left impacted.

FIGS. 1 and 2.—Dr. Roxburgh's male case for diagnosis.
? Poikiloderma Jacobi: ? Atrophic lichen planus.

FIG. 3.—Dr. Roxburgh's female case for diagnosis,
showing patchy pigmentation on buttocks, shoulders,
upper arms and right elbow.
(Photographs by Dr. A. C. Roxburgh.)

FIG. 1.

FIG. 2.

FIG. 3.

Dr. Freudenthal: Section (Fig. 3) shows capillary vessels markedly increased in papillary body. Perivascular oedema and slight infiltration. Melanin considerably increased, especially in basal layer. No iron. The sections suggest that the case is primarily a vascular disturbance which has led to an increase in melanin production.

Section of Surgery

President—ERNEST FINCH, M.D., M.S., F.R.C.S.

[March 6, 1946]

DISCUSSION ON VASCULAR INJURIES IN WAR

Mr. J. J. Mason Brown: You have done me the honour of inviting me to open this discussion because I represent the Field Vascular Injuries Centre established in C.M.F. in April 1944. Because of a variety of factors—the site of the centre in a base hospital, the impossibility of segregating all cases from a long front in one centre and the inadvisability of evacuating cases in the hæmatoma stage over long distances—only a proportion of the vascular injuries were received. It is therefore impossible to give any estimate of the relative frequency of arterial injuries or to give the views of the forward surgeon from a consideration of the work of the special unit. Table 1 summarizes the cases admitted. Apart from isolated examples the traumatic arterial lesions fall into two groups: (1) Those in which surgical treatment of the arterial injury had already been carried out—primary ligations; (2) cases of traumatic aneurysm.

TABLE 1.—CASES ADMITTED FIELD VASCULAR CENTRE C.M.F. APRIL 1944 TO SEPTEMBER 1945

Lesion	British	Others	Total
Primary ligations, larger arteries ...	21	0	21
Primary arterial suture ...	1	0	1
Arterial contusion and thrombosis ...	0	1	1
Complete division of artery ...	1	0	1
Traumatic aneurysm ...	39	39	78
Trench foot and frostbite ...	11	24	35
Vascular diseases ...	27	12	39
Total, all cases	100	76	176

From the outset our approach to the problem was influenced by the depressing results of primary ligation of the main limb vessels quoted in the surgical literature of the last war and by the statistics given by Ogilvie and Stout at a surgical conference in Cairo. That the results of primary ligation even in very experienced hands were not significantly altered in the later stages of the Italian campaign is shown by the figures kindly given to me by Lieut.-Colonel C. G. Rob which comprise the cases of arterial injury encountered by him in his last battle period with a Field Surgical Unit:

Artery	No.	Results
Common iliac	1	Died, gas gangrene
External iliac	2	1 death, 1 below-knee amputation
Femoral	3	2 above-knee amputations
Popliteal	6	4 amputations
Subclavian	1	Amputation
Axillary	2	Both satisfactory
Brachial	1	Amputation
All cases	16	2 deaths, 9 amputations

In addition during the same period six lower limb and three upper limb amputations had to be carried out for purely arterial lesions because of the prolonged pressure of tourniquets.

Stanimers (1945) at a surgical conference in Rome gave the following figures from the Eighth Army front:

Femoral ligations 31, amputations 21 or 68%
Popliteal ligations 36, amputations 26 or 72%

An analysis of the 21 cases of primary ligation in our series shows that 16 involved the brachial (6), femoral and popliteal (5 each) arteries. Six amputations had been carried out before admission, seven had limbs severely crippled by ischæmic changes and in only three cases (2 brachial) were the results really good.

The almost constant laceration and the extensive intimal damage occurring in arterial wounds make primary suture possible on rare occasions. One such case, operated on by Lieut.-Colonel G. Blackburn, was admitted. Although the lateral suture of the popliteal artery had resulted in thrombosis a day or two after operation the circulation was well established and Professor Learmonth informs me that the final result is exceedingly good.

In the M. R. C. memorandum on Arterial Injuries (1944) it was suggested that it might be possible to make a musculo-fascial barrier over the injured vessel and the records of two cases are of some interest.

On the analogy with kraurosis vulvæ, which appears to respond well to oestrogens, I gave my patient an ointment containing testosterone. He says that there is already an improvement.

POSTSCRIPT.—Dr. Prosser Thomas tells me this case is identical in appearance with the one shown by him before this Section in May 1945 (*Brit. J. Derm.*, 58, 22) under the diagnosis of morphœa of glans penis (which I regret I missed seeing). The histology reported then would seem to me quite compatible with a diagnosis of lichen sclerosus, a point made in the discussion by the late Dr. Klaber. Dr. Prosser Thomas's case appears to have followed the same course as mine and there was apparently no urethral atresia.

Dr. Prosser Thomas: The clinical appearances are the same as in my case, as was the history of blister formation, sometimes hæmorrhagic and painful. My patient had had no thorium X or other form of radiation. Freeman and Laymon (1941, *Arch. Derm. Syph.*, 44, 547) studied 18 cases of "Balinitis Xerotica Obliterans" and thought the condition could be differentiated from scleroderma histologically. They could not determine any relationship with circumcision in any of the patients, but found urethral stenosis present in all. In a later study (*Arch. Derm. Syph.*, 1944, 49, 57) they concluded that the disease is identical with lichen sclerosus atrophicans.

Dr. R. T. Brain: I regard this case as one of lichen sclerosus which may be a variety of lichen planus although Ormsby and Montgomery describe lichen sclerosus as a separate entity. It is possibly related to morphœa.

Chronic Burrowing Ulcers of the Leg.—H. J. WALLACE, M.D.

Mrs. A. G., aged 45, a Maltese. She lived in Malta until eight years before the onset of the present trouble. In March 1944 she struck her left leg on a nail while at work. This caused a small wound which bled and did not heal but gradually enlarged and was resistant to out-patient treatment for six months. The patient was admitted to St. Thomas's Hospital under the care of Mr. R. H. Boggon, and resolution occurred within the course of a few weeks. Investigations at this time showed no evidence of varicose veins: blood Wassermann reaction negative; an X-ray of the underlying bone showed slight inflammatory change only consistent with the overlying ulcer of some size. Biopsy of the edge of the ulcer showed an acute and chronic inflammation. In May 1945 the original ulcer recurred and since then other ulcers have formed on both legs. The appearance of the subsequent ulcers has been characteristic of those described as chronic burrowing ulcers of the skin and an anaerobic streptococcus has been isolated on two occasions from fresh ulcers, after further organisms such as *Staphylococcus aureus* and *B. pyocyaneus* previously isolated from the ulcers had been inhibited by local application of iodine. At no time has tubercle bacilli been found either on direct examination or culture. Since the condition relapsed some eight months ago she has been treated with penicillin and sulphonamides both systemically and by mouth, also with various antiseptic preparations, including a Bunyan bag with hypochlorite, without any permanent improvement. She is due to be admitted to St. Thomas's Hospital for further treatment probably with zinc peroxide.

I am showing this case partly because I do not believe this type of infection is common and partly because I want to prove the diagnosis is correct. A further reason for showing this patient is in connexion with the Workmen's Compensation Act. Most of these cases are described as occurring after trauma, which may vary from an abrasion to an operative wound. According to the literature prognosis is variable, but at best treatment is likely to be prolonged.

Dr. A. C. Roxburgh: It seems rather an absurd suggestion when the condition is on the leg, but the honey-coloured exudation through holes in the skin reminds me of lymphogranuloma inguinale (Nicolas-Favre disease). I do not know whether that could be considered.

Dr. A. Burrows: From the point of view of Workmen's Compensation I may point out that the original injury was to the left leg, not to the right—at least that was the story which the patient gave—but it was on the right leg that the ulcer developed.

Dr. R. T. Brain: I think it is possible that some of these obscure chronic ulcerative lesions are maintained by inflammatory reactions in the subcutaneous fat, i.e. fat necrosis.

Dr. W. N. Goldsmith: What does Dr. Wallace think is the nature of the dark purplish spots on the foot. The whole foot appears swollen. Has Kaposi's hæmorrhagic sarcoma been entirely excluded?

Dr. Wallace, in reply: Some of these bluish nodes have been observed to break down and form sinuses comparable with the sinuses formed elsewhere. There is one point to be mentioned in connexion with compensation: the original ulcer on the left leg undoubtedly followed trauma.

Treatment.—As already stated this was influenced by the results of the primary ligations we had seen. It was felt that sooner or later operation would be required in emergency and that arterial repair would be the only method likely to secure a fully functioning limb. In the early cases, therefore, suture was carried out when technically possible even in the presence of a good collateral circulation in order that technical skill might be acquired and so enhance the chances of success in cases in which it was vitally necessary. For this reason the number of suture operations is high.

The ischæmic or potentially ischæmic limb.—The limb was kept at rest outside the bedclothes and exposed to a cool environmental temperature, fans being in constant use during the summer months. It was kept in the position which was observed to give the maximum circulation, usually about six inches below heart level. The limb was slightly elevated on itself in cases in which there was peripheral œdema; otherwise it was kept level or slightly dependent to produce moderate venous congestion. Reflex vasodilatation was employed as a routine and was supplemented in the earlier cases by paravertebral nerve blocks and, after operation, by repeated doses of morphine. Penicillin was used liberally in the control of infection in the associated wounds and in wounds distal to the lesion.

Indications for early operation.—The indications for operation before the development of the maximum collateral circulation were: (1) External hæmorrhage; (2) increase in the size of the swelling associated with increasing peripheral ischæmia; (3) suppuration at the periphery of an arterial hæmatoma; (4) secondary hæmorrhage; and (5) in very large hæmatomata because of pressure on the potential collateral vessels or because of severe pain not relieved by sedatives. Mistakes were made in three popliteal lesions in which operation was carried out because of the rapid enlargement of the swelling and all were found to be gross local dilatations of the vein in aneurysmal varices—an error to which Makins (1919) drew attention in the last war. Fortunately transvenous suture was successful in each case. Emergency operations were carried out in five cases in which the lesion found was identical with that recently described by Paterson Ross (1946), viz. a mass of blood clot surrounded by fluid blood within a thin sac wall derived from the surrounding connective tissues. The emergency arose with dramatic suddenness in every case and they were regarded as cases in which the original sac had become detached from the margins of the arterial opening and further bleeding had occurred around its periphery.

Arteriography.—No complications followed its use, the technique employed being similar to that described by Learmonth (1944). This diagnostic method gives reliable evidence of the extent of the collateral circulation and may also be of value in localizing the site of the arterial injury. It is unfortunately of little value in old-standing cases of aneurysmal varix merely showing a faint outline of the grossly dilated vein (figs. 2, 3, 4). It was carried out in a few cases of large hæmatoma and here it confirms the clinical finding that there is always some circulation through the affected vessel.

Heparin.—Heparin was employed after arterial suture operations but was not employed after transvenous suture of aneurysmal varices. Its control by body-weight was very uncertain and different batches seemed to vary in their potency so that repeated estimations of the coagulation time had to be carried out day and night. In cases in which there was no contra-indication to its use a pre-operative test dose was given and the post-operative dosage calculated from it.

The operations carried out in 62 cases were as follows:

(1) Emergency operations carried out before full development of the collateral circulation:	(3) Operations on main vessels:
Direct ligation and division	Direct ligation and division
Arterial suture	Arterial suture
Proximal ligation	Aneurysmorrhaphy
	Ligation of fistula
	Ligation of neck of sac
23	25
(2) Operations on minor vessels (those whose ligation is usually safe):	
Excision	9
Quadruple ligation	3
Arterial suture	1
Aneurysmorrhaphy	1
	14

CASE I.—Sgt. I. S., aged 32, sustained a large wound of the popliteal fossa with severe external bleeding which required the application of a tourniquet for its control. The tourniquet was loosened at intervals and, ten hours after wounding, four pints of blood were transfused and the wound was excised. As the surgeon could feel the artery pulsating it was not explored. Eight hours later there was another brisk hæmorrhage which could only be arrested by the application of a tourniquet; two pints of blood were transfused, the wound was inspected and a superficial vein was ligated. Three days later the wound, which measured 7 by $4\frac{1}{2}$ in., was closed by suture. Five days after this operation there was another brisk hæmorrhage but this had stopped when he reached the theatre and two days later a superficial hæmatoma was evacuated without incident. On the fourteenth day after wounding, the patient noted throbbing and pulsation behind his knee. On his admission to the vascular centre there was a large varicose aneurysm of the popliteal vessels but his leg was not affected by ischæmia (fig. 1).

CASE II.—Cpl. R. M., aged 34, was wounded on a commando raid and could not be evacuated to the Italian mainland for thirty-six hours. He was admitted in a routine convoy forty-eight hours after wounding with through-and-through wounds of the thigh. The femoral artery was contused but not thrombosed and a musculo-fascial barrier was formed over it. A delayed traumatic aneurysm resulted and was treated at a later date with success and the limb was unaffected by ischæmic changes.

Only two cases but they serve to show the practical nature of the method. They also emphasize the need for retaining such cases under constant supervision and delaying their evacuation until the wounds have healed and the danger of further bleeding is over.

The results of primary ligation quoted do not take into account the severity of the associated soft tissue wounds. Arterial wounds fall into two main classes:

(1) *Those associated with large soft tissue wounds and severe external hæmorrhage.*—There is often severe damage to the potential collateral vessels. Such cases demand urgent surgical treatment which, in view of the almost inevitable laceration of the vessel wall, will result in ligation unless some means of restoring the circulation such as a type of Tuffier's tube or Blakemore's vein graft is employed. Restoration of the circulation in a limb whose blood flow has been interrupted for a considerable time leads to the rapid absorption of the products of disordered metabolism from it and may endanger the life of the patient. Further work is required before such methods can be brought into general use and until then the need for amputation following primary ligation in such cases should not be regarded as failure but as the price some patients have to pay for life-saving surgery.

(2) *Arterial wounds associated with trivial wounds of entry, with through-and-through wounds or occurring in multiple peppering with small fragments.*—This type is characterized by bleeding into the tissues and the clinical recognition of the arterial wound is of the utmost importance. The benefits of full wound excision can only be secured at the expense of the abrupt interruption of the blood flow, for ligation will be necessary in most cases. Despite the arterial injury there is always a flow of blood through the vessel and it is often sufficient for the peripheral pulses to be felt. All such wounds should be auscultated: the presence of local swelling and a systolic murmur are indicative of arterial

TABLE II.—78 CASES OF TRAUMATIC ANEURYSM.

wounding and operation should be delayed until the collateral circulation has become established in the absence of definite indications for earlier intervention. In the absence of local swelling and murmur failure to feel the peripheral pulses indicates complete division of the artery, contusion followed by thrombosis or traumatic arterial spasm and only exploration can establish the diagnosis.

Table II gives the details of the 78 cases of arterial injury of this type admitted to the Field Centre. Spontaneous cure resulted in two cases: (1) An aneurysmal varix of the superficial femoral artery, and (2) a small false aneurysm of the common carotid artery.

It is of interest to note that arterial suture was only possible in three of the emergency cases, an experience directly contrary to that of those who advocate early operation and repair.

Dissection was most difficult three to four weeks after wounding and was always more difficult in the larger lesions because of the increased fibrosis. In arterial and varicose aneurysms the false sac was opened and further dissection was carried out from within. Portions of the sac wall were never used to repair the vessel although in some cases after lateral suture of the arterial opening the suture line was reinforced by bringing the sac wall together over it. No attempt was made to remove the sac wall when important structures were incorporated in it and in cases in which its removal seemed likely to damage collateral vessels. Arterial branches entering the aneurysm were occluded by suture from within the sac. The companion vein was not ligated unless it was so damaged that its ligation could not be avoided.

Lumbar ganglionectomy was employed in one case in which the common iliac artery had to be ligated but apart from this case and a case of posterior tibial aneurysmal varix admitted after sympathectomy had been performed, sympathectomy was not carried out.

The control of hæmorrhage at operation.—A tourniquet was employed in arterial and varicose aneurysms but its use was given up in aneurysmal varices after failure to cure a posterior tibial fistula. When the site of the lesion precluded the use of a tourniquet the artery was exposed and temporarily secured above the lesion, and in all cases in which hæmorrhage was liable to be considerable an intravenous infusion was begun before operation in order that transfusion could be started immediately when required. Fresh blood was always used.

The results of treatment.—In the 62 operations there was one death following ligation of the common iliac artery just proximal to a huge lesion of the external iliac artery. The hæmatoma was pressing on the iliac vein. Following the operation the tension of the swelling was greatly reduced and twelve hours after operation the patient collapsed from overwhelming toxæmia probably from the absorption of metabolites from the limb.

In one axillary lesion operated on in emergency in which ischæmic changes were already present these were increased and gangrene of two digits occurred. Recurrence followed three weeks after operation in the case in which the fistula was ligated.

In the remaining cases there were no complications and secondary hæmorrhage after operation did not occur. In the suture operations the peripheral pulses were never lost whereas following direct ligation, even as long as two years after wounding, they were always absent for some days after operation. In three cases in which arteriography was carried out some eight weeks after arterial suture the arteries were shown to be patent and there was no sign of the development of a collateral circulation. In one of these cases the arteriogram showed a dilatation like a plumber's wiped joint at the site of the transvenous suture although this gave no signs on clinical examination (fig. 5).

A military surgeon can of necessity quote only immediate results and the correctness or otherwise of our approach to the problem can only be assessed by a long term follow up. It is to be hoped that this may yet prove possible at least in the British cases.

From the work of the special centre the following conclusions seem justifiable.

- (1) The initial treatment of arterial wounds associated with minor soft tissue wounds should be conservative.
- (2) Wounds in the vicinity of large vessels should always be auscultated before primary surgery is carried out.
- (3) Operation should be delayed until the collateral circulation is fully established in the absence of definite indications for earlier intervention.
- (4) The nature of the operation to be carried out can only be decided when the exact pathology has been displayed and assessed.
- (5) In arterial and varicose aneurysms a tourniquet should be employed. If this be impossible the proximal artery should be controlled provisionally as the first step in the operation and arrangements made for the immediate giving of blood.
- (6) The care of the potentially ischæmic limb is of the utmost importance and reflex vasodilatation is of definite value.
- (7) The blood volume should be restored to normal as soon as hæmorrhage is fully controlled.

Arterial hæmatomas.—These were treated by ligature proximal and distal to the wounded point, with the addition of endo-aneurysmorrhaphy if any branch opened into the sac. If the sac dissected easily, as a general rule it was removed, but we had no hesitation in leaving the sac if it appeared possible that the dissection would risk collateral vessels. On one or two occasions we were chagrined to find that the cause of a lesion, which we had believed to be an injury to a peripheral nerve, was the existence of an arterial hæmatoma; for example in a case in which a false aneurysm of the thoracic axis had formed between the two heads of the median nerve. I believe it to be important that the ligatures should be placed as close as possible to the injured segment, and I do not agree with Holman (1944) that the proximal ligature should be placed just distal to the largest visible collateral. In our experience when an artery is cleanly divided between ligatures, the proximal clot is short and there seems no reason to doubt that branches too small to be seen at operation may subsequently enlarge to provide a proportion of the collateral circulation.

We have been specially interested in arterial aneurysms in the neck. On one occasion we had to deal with an aneurysm at the origin of the external carotid in which the foreign body had entered from the opposite side and had traversed the pharynx. The problem of access to more proximal aneurysms has not always been easy to solve. In one case in which a very large aneurysm having its origin in a wound of the third part of the subclavian artery extended into the superior mediastinum, the inner end of the clavicle and the upper part of the sternum were removed piecemeal subperiosteally, and we were glad to find that after this rather mutilating procedure function was very little impaired. In dealing with aneurysms of the common carotid artery for which ligature was likely, we have first performed a sympathectomy on the opposite side, and after seven days treated the aneurysm and done a sympathectomy on the same side in order to provide immediate maximal dilatation of collateral channels. In ligating the left common carotid artery at its origin from the aorta, a technical point of some importance is to ensure, by temporary occlusion of the vessel and palpation of the radial pulse, that one is not dealing with a left innominate artery.

Arteriovenous aneurysms.—The side-effects of these are well known. The earliest date at which we have detected cardiac enlargement is two months after injury. That the degree of cardiac enlargement depends on the size of the communication is shown quite well in a case in which two fistulæ were present. After dealing with the one between the superficial femoral artery and vein, the cardiac size diminished. We found, however, that a thrill and murmur still persisted, and six months after the first operation the heart had begun to enlarge again. At a second operation, a fistula between the profunda and the femoral vein was repaired.

With regard to the Branham phenomenon, my colleague Mr. Maybury communicated to me the acute clinical observation that while the diminution in pulse-rate followed immediately on the obliteration of the fistula, the return to the previous rate was a more gradual process, and this we verified by making a combined sound track and electrocardiogram in a patient who had a fistula between the medial circumflex artery and the profunda vein. Many of these patients show a relative polycythæmia as well as an increased blood volume, and in many the hæmoglobin content of the individual corpuscle is increased.

With regard to treatment, we have noticed spontaneous healing in one case in which a fistula had existed between the brachial artery and vein. Like other workers, we have seldom found it possible to carry out reparative surgery.

We have had a number of interesting anatomical types. In one case two fistulæ were present close to each other between the popliteal artery and vein. In a second case, which I have recorded (1945), both the common carotid and vertebral arteries contributed to the fistula. Ligation of both these vessels in a man of 43 was not followed by any untoward effect. In a third, a revolver bullet had completely divided the common carotid artery, and nine months afterwards at operation we found the distal end thrombosed while the proximal end communicated through a sac with a large opening in the internal jugular vein, thus giving rise to what was at least a partial reversal of the cerebral circulation as evidenced by unilateral swelling of the face and conjunctival venous stasis. This patient did well after operation.

Like other workers, we have had a patient with an arteriovenous aneurysm who did not know that he had been wounded. In none of our cases of arteriovenous aneurysm have we been able to detect any further nutritional change, either superficial or deep, after treatment by quadruple ligation and excision.

Mr. A. M. Boyd: My experience of vascular injuries is limited to those cases referred to a Base Hospital in Egypt between October 1942 and October 1945. Altogether 28 aneurysms were treated. A few recent injuries to blood-vessels from local accidents were seen. There were a few cases of secondary hæmorrhage. Altogether 41 main vessels were ligated for one reason or another.

Ligature of the main artery of a limb carries with it a considerable risk of gangrene. Sir George Makins collected a series in World War I in which the primary artery had been ligated and the fate of the limb left to the collateral blood flow.

The percentage of cases complicated by gangrene according to arteries involved were as follows: Subclavian 25%; axillary 16.6%; brachial 23%; femoral 25%; popliteal 41.6%.

Apart from frank gangrene depleted blood flow leads to ischæmic necrosis of muscle and fibrosis, wasting of muscles and nerve palsies. Even if these grosser manifestations are not seen inadequate blood supply to the muscles is revealed in the lower extremities by intermittent claudication. The fate of the limb after ligature of a main artery depends upon the collateral circulation. Every effort must be made to expand it quickly and blood-pressure must be kept up. The limb should be kept below the level of the heart by blocks under the head of the bed.

The limb should be kept cool to reduce metabolism and the rest of the body warm to aid sympathetic release.

The quickest method of dilating the collateral circulation is by sympathectomy. It has been practised in America for many years. Gage of New Orleans has carried out sympathetic block in all cases of traumatic injuries to blood-vessels and in operations upon aneurysms since 1930 without the occurrence of a single case of gangrene. Doubt has been cast upon the efficacy of this procedure by theoretical considerations. It has been stated that experimental stimulation of the sympathetic leads to vasoconstriction in the artery but increased blood flow to the muscles. Blocking the sympathetic would therefore reduce the flow to muscle.

Theis, however, has shown convincingly by animal experiment that sympathectomy increases the total inflow to a limb and also increases the collateral circulation after ligature of the main vessel.

Barcroft has recently shown that there are vasoconstrictor fibres in the muscles of man. Clinically it is well known that sympathectomy will improve intermittent claudication proving that the blood supply to the calf muscles has been improved.

I have ligated 41 main vessels. In 40 of them a sympathectomy was carried out either at the time of ligature or a fortnight before. Most of them were not simple ligations but extensive excisions of long segments of artery. In this series there was one example of gangrene following an excision of an arteriovenous aneurysm in Hunter's canal.

In one case of arteriovenous aneurysm of the first part of the right subclavian, sympathectomy was impracticable on account of dense adhesions round the apical pleura. Operation was followed by ischæmic necrosis of the forearm muscles.

In traumatic false aneurysm the artery was ligated on either side of the sac, the sac opened, clot turned out and subsidiary vessels ligated. As much of the sac wall that could be removed with safety was excised. A sympathectomy was carried out in each case.

Time of operation.—It is undoubtedly wise to wait three months before operation is undertaken, but in my experience it is seldom possible. In all but two cases, operation had to be carried out much earlier on account of bleeding, pain from pressure on nerves or infection.

In arteriovenous aneurysm quadruple ligature with excision of aneurysm when practicable, accompanied or preceded by a sympathectomy, was performed. There was one case of gangrene after an extensive excision of an aneurysm in Hunter's canal.

My experience leads me to believe that the safest method of ensuring an adequate collateral circulation is by releasing vasoconstriction by sympathectomy.

Professor J. R. Learmonth: My part in this discussion is to give some account of the work at a vascular centre established in an Emergency Medical Service hospital by the Department of Health for Scotland. In general, we were not confronted with acute problems, except after D-day when we saw a few cases; the majority of our patients were seen some months after wounding.

(4) The way in which Professor Learmonth has applied to clinical surgery the observations of Sewall, Sandford, François Franck and later Stewart is of great interest. He has been able to produce vasodilatation in the affected limb by warming the opposite healthy limb, or even by warming the other limbs.

In this connexion, I wish to emphasize a point which seems to be of real interest. It is that simple obliteration of the main blood supply of the limb, whether by localized compression or by ligature, does not produce any vasoconstriction, but it does produce a considerable degree of vasodilatation comparable to that which is produced by lumbar ganglionectomy (figs. 1 and 2). This vasodilatation is constantly progressive and entails a fall of peripheral pressure which becomes more and more accentuated as the experiment proceeds; it is this which ultimately causes serious harm to the vitality of the tissues.

It is therefore obvious that any form of sympathectomy can only exaggerate the vasodilatation already produced by the arterial ligation. Its purpose would be to increase the proximal collateral circulation, but it produces at the same time a more marked vasodilatation.

Experiments have been made on dogs showing that disturbances in the peripheral circulation, following the ligature of the external iliac artery, disappear immediately after lumbar ganglionectomy; but they do not disprove our statement.

We have shown in different papers that the arterial circulation of the hind leg of a dog cannot be compared with that of a man, as long as the sacral aorta is functioning. We have further shown that in the normal dog the simple ligature of the external iliac artery very often does not produce any disturbances in the peripheral circulation, or, if it does, they are merely transitory. Circulation is restored without delay by way of the anastomoses, particularly by the main branches of the sacral aorta. To reproduce experimentally on a dog the conditions which exist in a man it is indispensable to begin by ligature of the sacral aorta. Many erroneous conclusions have been published, because their authors have not taken this fundamental point into account.

During the last war Oppel in Russia and Sir George Makins in this country recommended the ligation of the accompanying vein even when the lesion only involved the artery, and experience has shown that the results are thereby improved.

Fig. 3 shows that the peripheral pressure is higher on the side of the double ligature and the manometric readings even show respiratory and cardiac oscillations. How then does ligature of the corresponding vein produce its effects? Are they important and really useful?

Probably most workers in this field think that venous ligature simply produces a hydrostatic barrier limiting the flow of blood from the limb and thus raising the pressure in the capillary bed.

Our experimental work has shown us that the response to ligature or compression of the vein is extremely complex. It produces first a fall (fig. 4) in peripheral pressure which is rapidly succeeded by a rise. Arteriography has shown that this double reaction in reality is composed of two elements, vasoconstriction and vasodilatation, which do not simply follow each other but are coincident, associated and combined. Venous ligature produces a gross dilatation in the small vessels and a vasoconstriction in the main arteries and their large branches.

Besides the limitation of blood supply, the danger of obliteration of a main artery seems to lie in the general progressive diminution of peripheral pressure, which results from vasodilatation. Ligature or compression of the corresponding vein leads to a vasoconstriction which raises the peripheral pressure to a more normal level. Since this vasoconstriction only involves the large vessels, while the small vessels are dilated, the vitality of the tissues is markedly improved.

Of course, there is no need to use the ligature of the companion vein in all cases of ligature of the main artery. But there is a point of real importance in our statements, which is that the vasomotor reactions to the ligature or obliteration of the vein are quite independent of the nervous system, either central or peripheral. The patients may, therefore, benefit from these vasomotor reactions, even when one or all the nerves of the limb have been cut.

The main indication for ligature or compression of the companion vein will be particularly clear in cases of very extensive injuries, with combined arterial and nervous lesions, where other techniques for inducing peripheral vasodilatation are ineffective.

Methods of examination.—We have rarely used arteriography in the localization of arterial hæmatomas, and the method does not lend itself well to the identification of the site of an arteriovenous fistula. We have made considerable use of an observation, also indicated to me by Mr. Maybury, that the murmur in an arteriovenous fistula can be heard in the arm of the observer when his hand is placed over the region of the fistula. By using this method of "auscultation at a distance" with the index finger as the exploring digit, we have been able to localize the maximum point of intensity of a murmur with considerable accuracy. Finally, except in carotid lesions, we have not employed sympathectomy on more than one or two occasions as a preliminary to ligation of a large vessel. It has seemed to us that the collateral circulation after two or three months has always been adequate, and we have attempted to avoid any immediate post-operative risk by reflex vasodilatation combined with the administration of morphia which appears to have a decidedly beneficial effect in reducing vasoconstrictor tonus. Our practice has been to wrap the limb on which the operation has been done in a sterile towel without any constricting bandage, and to leave it at room temperature with the head of the bed slightly raised to interfere somewhat with the venous return. We are satisfied with the results of this procedure, except that it has become apparent that we ought more often to have realized the importance of preserving, if possible, the main venous channels, a refinement to which attention has recently been drawn by Professor Paterson Ross (1946).

Vascular tumours.—One matter which may not have come within the experience of surgeons in vascular centres in the theatre of war is the occasional development of a vascular tumour following injury. We have had several such cases, and in most, but not in all, a small cutaneous hæmangioma has previously been present, a circumstance which lends support to Reid's (1925) view that hæmangiomas in general represent areas in which the primitive arrangement of vessels has not completely developed into its permanent form. One example will suffice. A pilot officer knocked his arm on the wing of his aeroplane, over the site of a small nævus, and eighteen months afterwards this area was the site of a large pulsating tangle of vessels fed by three large trunks containing arterial blood. The tumour involved the skin and sent communications to the intramuscular clefts. It lent itself to excision with a satisfactory result. I mention this type of case because I believe that other examples will turn up from time to time in the post-war period.

Professor F. Albert (Liège): My own clinical experience dates from the last war, since when I have been continuously interested in all aspects of the surgery and pathology of vascular lesions, the treatment of which has benefited in no small degree by the general progress brought about by the use of sulphonamides, heparin, and the discovery of penicillin.

It has been known for many years that the obliteration of a large artery is followed by vasomotor disturbances of critical importance. On the Continent at least there is a tendency to regard these reactions as being purely vasoconstrictor in origin, which therefore demand therapeutic measures in order to produce vasodilatation.

In the past there has been a general consensus of opinion that all obliterative arterial lesions, which are accompanied by irritation of the vessel wall, directly cause vasoconstrictor reflexes. This view has particular reference to trauma of the arteries which is followed by thrombosis, to arterial embolism and spasm. It even includes venous thrombosis, especially when accompanied by phlebitis.

To deal with these vasoconstrictive phenomena the most useful means at our disposal have been:

- (1) Resection of the thrombosed segment or removal of the embolus, which, if done early, also prevents extension of the thrombosis to the collateral vessels.
- (2) Infiltration of the appropriate sympathetic chain with novocain when the disease is acute, or, when the patient's condition permits, resection of the sympathetic chain in less acute or chronic lesions.
- (3) More recently peri-arterial infiltration with novocain, or even proximal intra-arterial injection of novocain has been used; and the latter is specially useful when obliteration is incomplete.

FIG. 3.—Dog weighing 28 lb. given 1.75 gramme chloralose intravenously. Ligation on the middle sacral artery. At (1) the left common iliac artery was ligated, and at (2) the right common iliac. At (3) the right common iliac vein was tied.

On the left side the peripheral pressure falls progressively for the whole of the experiment. On the right side it rises again rapidly after ligation of the vein and maintains a level much higher than the left; moreover the cardiac and respiratory oscillations reappear.

Between (5) and (6) the vena cava was occluded. Note the difference in vasomotor response between the right and the left. The right limb at first showed much more marked vasoconstriction than the left.

(From "A propos des ligatures veineuses. Etude expérimentale des réactions vaso-motrices périphériques", by F. Albert, *Lyon chirurgical*, 29, 273.)

Mr. B. C. Maybury gave the results of a preliminary "follow-up" of 34 patients suffering from traumatic false aneurysm and arteriovenous fistula treated at Park Prewett E.M.S. Hospital, Basingstoke. The arteries involved were internal and external carotid 1 case, first part axillary 2 cases, third part axillary 4, brachial 5, radial 1, common femoral 1, superficial femoral 7, profunda femoris 2, popliteal 9, posterior tibial 1, transversalis colli 1. To ensure an adequate collateral circulation, the general policy had been to wait two to three months in the upper extremity and three to four months in the lower before operation was undertaken, though sometimes the time of operation had to be advanced for the well-known indications of rapid increase in the size of the sac, hæmorrhage, pain, &c. Sympathectomy had not been performed on any patient, but the corresponding vein had been tied in all except one, even when a suture operation had been performed. Two patients had not been subjected to operation, one with an aneurysmal varix of the transversalis colli causing no symptoms, and the other with a popliteal aneurysm who was subjected to an injection of the superficial femoral with pyelectan for an arteriogram; as a direct result the femoral and popliteal arteries and the aneurysm thrombosed; he suffered a serious ischæmic myositis of the anterior tibial group but was able to walk.

In the whole series of 32 patients operated on neither gangrene nor ischæmic myositis had occurred and there had been no mortality. The absence of the latter was largely due to there having been no cases of aneurysms or fistulae at the root of the neck and

FIG. 1.—Normal arteriogram with some slight vasoconstriction.

FIG. 2.—Same animal after left lumbar ganglionectomy and compression of the right common iliac artery for six minutes.

FIG. 3.—Arteriogram taken after six minutes' compression of the right common iliac vein. There is vasoconstriction of the large vessels and dilation of all the small muscular branches.

FIG. 4.—The same preparation, larger size, showing details of the small vessels.

(These arteriograms are copied from "Les compressions vasculaires, Etude artériographique," by F. Albert, in the *Revue belge des Sciences médicales*, Vol. 9, No. 3.)

FIG. 3.—Dog weighing 28 lb. given 1.75 grammes chlotalosane intravenously. Ligation on the middle sacral artery. At (1) the left common iliac artery was ligated, and at (2) the right common iliac. At (3) the right common iliac vein was tied.

On the left side the peripheral pressure falls progressively for the whole of the experiment. On the right side it rises again rapidly after ligature of the vein and maintains a level much higher than the left; moreover the cardiac and respiratory oscillations reappear.

(From "Les oblitérations artérielles. Etude physio-pathologique", by F. Albert, in *Lyon chirurgical*, 29, 649.)

Between (5) and (6) the vena cava was occluded. Note the difference in vasomotor response between the right and the left. The right limb at first showed much more marked vasoconstriction than the left.

(From "A propos des ligatures veineuses. Etude expérimentale des réactions vaso-motrices périphériques", by F. Albert, *Lyon chirurgical*, 29, 273.)

Mr. B. C. Maybury gave the results of a preliminary "follow-up" of 34 patients suffering from traumatic false aneurysm and arteriovenous fistula treated at Park Prewett E.M.S. Hospital, Basingstoke. The arteries involved were internal and external carotid 1 case, first part axillary 2 cases, third part axillary 4, brachial 5, radial 1, common femoral 1, superficial femoral 7, profunda femoris 2, popliteal 9, posterior tibial 1, transversalis colli 1. To ensure an adequate collateral circulation, the general policy had been to wait two to three months in the upper extremity and three to four months in the lower before operation was undertaken, though sometimes the time of operation had to be advanced for the well-known indications of rapid increase in the size of the sac, hæmorrhage, pain, &c. Sympathectomy had not been performed on any patient, but the corresponding vein had been tied in all except one, even when a suture operation had been performed. Two patients had not been subjected to operation, one with an aneurysmal varix of the transversalis colli causing no symptoms, and the other with a popliteal aneurysm who was subjected to an injection of the superficial femoral with pyelectan for an arteriogram; as a direct result the femoral and popliteal arteries and the aneurysm thrombosed; he suffered a serious ischæmic myositis of the anterior tibial group but was able to walk.

In the whole series of 32 patients operated on neither gangrene nor ischæmic myositis had occurred and there had been no mortality. The absence of the latter was largely due to there having been no cases of aneurysms or fistulæ at the root of the neck and

only one of the internal carotid; the latter, an arteriovenous aneurysm of the internal and external carotid and jugular vein, treated by immediate proximal ligation of both arteries and a remote distal ligation of the external carotid (with ligation of the jugular vein) had been converted into an aneurysmal varix and, although the murmur was still present, it was less and not audible to the patient seven months later. The remaining 31 patients operated on had been cured of their arterial lesions.

Immediate proximal and distal ligation had been performed on 25 and arterial suture on 6. The latter figure was disappointing but as excuse there were only 6 aneurysmal varices, the remainder being made up of 17 varicose aneurysms and 11 false aneurysms and arterial hæmatomata. There is no doubt it is much easier to suture the hole in an aneurysmal varix than in either of the other two lesions; the hole is usually smaller and the absence of early extravasation of blood ensures the absence of a later fibrosis. Operating on an arteriovenous aneurysm meant for him at any rate two or three hours of "toil, blood and sweat" and he was only too thankful at the end of that time to get ligatures applied. Of the 6 suture operations, 3 were completely successful, 1 partially successful (thrombosis occurred ten days later) and 2 were failures as regards patency of the vessel.

The period between the operation and the "follow-up" varied from three weeks to sixteen months, but was mainly about nine months. In all cases where ligation had been performed the systolic and diastolic pressures were well below those of the opposite side, the former usually 20 to 40 mm.Hg and the latter 10 to 20 mm.Hg.

In the case of the upper extremity the frequency of associated nerve lesions often prevented an accurate estimation of the disability due to the arterial ligation, but in the case of the lower extremity the arterial lesion is more often uncomplicated. Several patients complained of intermittent claudication after walking two or three miles. In a few there was very slight œdema of the leg detected only by picking up a fold of skin and comparing its thickness with that of the opposite side. In several there was $\frac{1}{4}$ in. to $\frac{1}{2}$ in. increase in the girth of the leg at calf level. He was rather inclined to explain these two changes as being due to a local "starvation œdema" rather than to the vein having been tied. It was of interest to note that two of the three patients who had had successful suture operations showed no œdema although the vein had been tied, while the third, although showing slight œdema, had had a fractured femur. Only one patient showed any evidence of superficial varicose veins.

It was clear that all these patients have useful limbs which, however, have a lower circulatory reserve and will not stand up to heavy and prolonged work.

His object in giving these results was to provide a series of cases in which sympathectomy had not been performed, but in which the vein had been tied, for comparison with a similar series in which sympathectomy had been done and the vein not tied, which he hoped someone else would produce.

He wished to thank his colleagues, Messrs. White, Innes and Sames, and particularly Mr. Denys Williams, who had been responsible for the records.

He was very interested in Mr. Mason Brown's report of cases in which he had made use of a musculo-fascial barrier in the early treatment of a partial division of an artery. He had used this procedure himself in the last war and it was also of value in the lesion known as *contusion* without thrombosis when a portion of the arterial wall was apt to give way up to the 21st day: the barrier converted what would otherwise be a secondary hæmorrhage into an arterial hæmatoma, thus affording time for some collateral circulation before ligation.

He had been impressed by the term "parasitic circulation" first used by Holman to describe that part of the circulation which flowed from the heart through an arteriovenous fistula back to the heart. It covered, but did not explain, the known facts, viz. the cardiac enlargement, the arterial enlargement on the proximal side, the enlarged vein and the increased blood volume. The term deserved to be more widely known and used.

JOINT DISCUSSION No. 2

Section of Medicine with Section of Surgery

Chairman—T. IZOD BENNETT, M.D., F.R.C.P.

(President of the Section of Medicine)

[January 29, 1946]

DIAGNOSIS AND TREATMENT OF CHRONIC CHOLECYSTITIS

Dr. Maurice Shaw: From the point of view of treatment it is useful to regard chronic cholecystitis as occurring in two main forms, one an interstitial inflammation involving the wall of the gall-bladder and the other a catarrhal condition in which, at first at any rate, the walls are not greatly, if at all, involved. In the former type stone formation is common and gross disturbance of function can frequently be demonstrated by cholecystography; in the latter radiological examination may be completely negative.

An interesting point in the symptomatology of patients with gall-bladder disease is the gastric flatulence. This is almost certainly not the result of any actual excess of gas in the stomach as such patients are not aerophagists. The true explanation may be that the sensation of fullness is the result of an increase in gastric tonus causing the normal air content of the stomach to exert an undue pressure on its walls. The high intra-gastric tension which results is, of course, relieved by the eructation of some of this gas.

Probably one of the most controversial points in the diagnosis of cholecystitis is the question whether the absence of positive radiological signs can be taken to exclude disease of the organ. It is still the custom of some radiologists to report that the gall-bladder is normal but I cannot believe that it is possible to be sure that a gall-bladder is really radiologically normal by merely inspecting the shadow cast by an opaque material in its interior. We should not expect X-rays to show the presence of a pyelitis after intravenous pyelography and the analogy between this condition and what I have called catarrhal cholecystitis is a close one. It is in these cases that the clinical signs combined with such ancillary methods as duodenal intubation must be relied upon to provide the diagnosis but it must be confessed that it is impossible to attain anything like certainty in a fairly large proportion of cases. In these the therapeutic test must often be applied. When treatment has failed to alleviate the patient's symptoms the decision may have to be made as to surgical treatment even in the absence of demonstrable abnormality. It is in such cases that surgeons are often reluctant to operate but I do not think there can be any doubt that many such patients respond well to surgical treatment although their selection must always be a matter of great difficulty and, until more precise diagnostic methods have been introduced, we shall continue to experience disappointments.

In the case of interstitial cholecystitis it is hardly ever possible to achieve much by medical treatment but there does seem a possibility that in the future a combination of

only one of the internal carotid; the latter, an arteriovenous aneurysm of the internal and external carotid and jugular vein, treated by immediate proximal ligation of both arteries and a remote distal ligation of the external carotid (with ligation of the jugular vein) had been converted into an aneurysmal varix and, although the murmur was still present, it was less and not audible to the patient seven months later. The remaining 31 patients operated on had been cured of their arterial lesions.

Immediate proximal and distal ligation had been performed on 25 and arterial suture on 6. The latter figure was disappointing but as excuse there were only 6 aneurysmal varices, the remainder being made up of 17 varicose aneurysms and 11 false aneurysms and arterial hæmatomata. There is no doubt it is much easier to suture the hole in an aneurysmal varix than in either of the other two lesions; the hole is usually smaller and the absence of early extravasation of blood ensures the absence of a later fibrosis. Operating on an arteriovenous aneurysm meant for him at any rate two or three hours of "toil, blood and sweat" and he was only too thankful at the end of that time to get ligatures applied. Of the 6 suture operations, 3 were completely successful, 1 partially successful (thrombosis occurred ten days later) and 2 were failures as regards patency of the vessel.

The period between the operation and the "follow-up" varied from three weeks to sixteen months, but was mainly about nine months. In all cases where ligation had been performed the systolic and diastolic pressures were well below those of the opposite side, the former usually 20 to 40 mm.Hg and the latter 10 to 20 mm.Hg.

In the case of the upper extremity the frequency of associated nerve lesions often prevented an accurate estimation of the disability due to the arterial ligation, but in the case of the lower extremity the arterial lesion is more often uncomplicated. Several patients complained of intermittent claudication after walking two or three miles. In a few there was very slight œdema of the leg detected only by picking up a fold of skin and comparing its thickness with that of the opposite side. In several there was $\frac{1}{4}$ in. to $\frac{1}{2}$ in. increase in the girth of the leg at calf level. He was rather inclined to explain these two changes as being due to a local "starvation œdema" rather than to the vein having been tied. It was of interest to note that two of the three patients who had had successful suture operations showed no œdema although the vein had been tied, while the third, although showing slight œdema, had had a fractured femur. Only one patient showed any evidence of superficial varicose veins.

It was clear that all these patients have useful limbs which, however, have a lower circulatory reserve and will not stand up to heavy and prolonged work.

His object in giving these results was to provide a series of cases in which sympathectomy had not been performed, but in which the vein had been tied, for comparison with a similar series in which sympathectomy had been done and the vein not tied, which he hoped someone else would produce.

He wished to thank his colleagues, Messrs. White, Innes and Sames, and particularly Mr. Denys Williams, who had been responsible for the records.

He was very interested in Mr. Mason Brown's report of cases in which he had made use of a musculo-fascial barrier in the early treatment of a partial division of an artery. He had used this procedure himself in the last war and it was also of value in the lesion known as contusion without thrombosis when a portion of the arterial wall was apt to give way up to the 21st day: the barrier converted what would otherwise be a secondary hæmorrhage into an arterial hæmatoma, thus affording time for some collateral circulation before ligation.

He had been impressed by the term "parasitic circulation" first used by Holman to describe that part of the circulation which flowed from the heart through an arterio-venous fistula back to the heart. It covered, but did not explain, the known facts, viz. the cardiac enlargement, the arterial enlargement on the proximal side, the enlarged vein and the increased blood volume. The term deserved to be more widely known and used.

iodophenolphthalein, now known as iodophthalein B.P. Its isomeride sodium phenol tetra-iodophthalein has not been manufactured in this country and it has scarcely been used here. Recently, an entirely new contrast medium, hydroxy-iodophenyl-phenyl-propionic acid, has been produced. The Medical Research Council in 1942 announced that the name of Pheniodol B.P. had been adopted for this compound, originally manufactured abroad. It is taken by mouth only. It disturbs the patient less than the phthalein compounds. The density of the shadow and the results are usually as good as those following the intravenous injection of iodophthalein. No better results have been obtained by the more complicated routines, often used because of the relative inefficiency of the so-called "dyes" when taken by mouth. It is usual to give the compound at night, and to make the examination next morning, the patient fasting.

The results of cholecystography can be divided into three groups:

(1) When the gall-bladder fills with and concentrates the opaque medium, contains no gall-stone or adenoma, &c., and contracts down after a fatty meal, it is radiologically normal.

(2) Though otherwise radiologically normal, it may empty slowly, whether it contracts or not. Even twenty-four hours after the fatty meal, much opaque material is often seen. Since using pheniodol, one has noticed this delayed emptying more frequently, possibly because of the greater density of the shadow. The gall-bladder is seen often, though not always, to shrink in size when gall-stones are present; even though afterwards the pathological report reads that the walls are thickened and fibrosed.

Does the emptying rate, and perhaps also the contractibility, mean more than the rapid or slow emptying rate of the otherwise normal stomach. Like the latter, it may vary in speed in the same person at different examinations. Is it more than a visible manifestation of an inward and mental state? a psychosomatic condition? In discussing the emptying rate and the contractibility of the gall-bladder, it seems curious that no reference is ever made to the possibility that the liver has made some more bile, and that this is entering and filling the gall-bladder.

(3) When the gall-bladder fails to fill with and to concentrate the opaque medium, four things may have happened:

(a) The medium may never have been extracted from the blood: so much of the liver must be destroyed before bile is no longer excreted, that in the clinical picture, attention is not likely to be focused on the gall-bladder.

(b) The medium, like the bile, may never have been able to leave the liver, or at any rate to reach the common bile duct and jaundice results. As a general rule, cholecystography is obviously contra-indicated in jaundice, though if carried out in some cases of infective hepatitis, a poor filling of a small gall-bladder may be seen. Again, clinically, it is the liver and not the gall-bladder that beckons.

(c) The iodine-containing bile may have been prevented from reaching the gall-bladder: in most cases by a calculus in the neck or the cystic duct itself, but adhesions, perhaps from a duodenal ulcer, or other causes may obstruct the duct to such an extent that "no filling" is reported, even though the gall-bladder itself is normal.

(d) Finally the mucous membrane of the gall-bladder may have lost its power to concentrate the bile, whether gall-stones are present or not, as in true cholecystitis.

A sub-division of this group is that in which the density of the shadow is less than normal—? a temporary or permanent but partial loss of function by the mucous membrane. The density may sometimes be greater, or less, at a second examination after a period of medical treatment. These are the cases which are so difficult to assess. If the shadow is below the average, has the mucous membrane partially lost its power to concentrate: (1) Because of a non-opaque calculus or other block which produces a partial stoppage and so a reduced entry of bile to the gall-bladder; (2) because the gall-bladder is unusually large and the same amount of opaque material spread over a broad area produces a lesser density; (3) because of inflammatory changes in the wall; (4) because of a temporary vasomotor or similar disturbance.

It would seem that radiologically one can only comment on this unsatisfactory group and leave the further analysis to the clinician.

The fallacies are: (1) Congenital anomalies.

Birds, fish, rodents, the horse, deer, camels, the rhinoceros and the elephant are said normally not to possess a gall-bladder. To Morgagni is given the credit of being the first

penicillin and sulphonamides may succeed in eradicating an infection which is too deep-seated to be affected by methods hitherto available.

The treatment, by medical means, of catarrhal cholecystitis can be considered under four headings: diet, drainage, disinfection and drugs. I have never seen any sound reason for withholding fats from patients with gall-bladder disease provided they can tolerate them—which, of course, is often not the case. The fat-free diet has come to be accepted from a misconception of the mechanism of cholesterol metabolism. There is no evidence, as far as I am aware, that the level of the blood cholesterol materially affects the cholesterol content of the bile nor, indeed, that the blood cholesterol can be significantly changed by high cholesterol feeding. Those conditions which are characterized by the highest blood cholesterol levels known to medicine, e.g. diabetes and nephrosis, are not associated with any particular tendency to the formation of gall-stones. It is true that certain patients spontaneously volunteer the information that they are intolerant of fats but close inquiry will often show that it is only certain types of fatty food which cause discomfort, particularly fried foods. Butter, eggs and cream are often surprisingly well tolerated. One of our main objects in treating an infected gall-bladder is free drainage and this can best be achieved by giving drugs and diet which stimulate emptying of the gall-bladder. For this purpose fats are especially useful and it has long been my own practice to encourage a diet rich in suitable fats to patients who are found to tolerate them well.

Of the drugs which promote drainage magnesium sulphate has the greatest reputation although the pharmacological evidence that this drug causes contraction of the gall-bladder is not entirely satisfactory. The therapeutic use of the duodenal tube has rather been abandoned in this country because it seems to be generally felt that the administration of magnesium sulphate by mouth is equally effective and causes less discomfort to the patient. In addition to the cholagogues, choleretic drugs such as decholin have a place in the treatment of gall-bladder disease by non-surgical biliary drainage.

For the purposes of disinfection the drugs which have been most widely used are the salicylates, hexamine and the sulphonamides. I have used hexamine and, judging by clinical results, with a fair degree of success but it is difficult to assess results without bacteriological control. It should be used in very large doses and stringent precaution must be taken to ensure that the urine is permanently alkaline for fear of damaging the kidneys. I have usually adopted the technique of giving a single large dose, as much as 200 grains, in the evening two hours after the last meal which must be taken reasonably early, say at 6 p.m. Thereafter nothing at all may be taken until a late breakfast the next morning. In this way a high concentration of the drug is maintained in the gall-bladder for a reasonably long time. Recent work has shown that the sulphonamides are excreted in the bile in therapeutically significant concentrations and their use is always worth while. The most useful drugs of this class are probably sulphathiazole and sulphadiazine.

Dr. G. T. Calthrop (*in absentia*, read by **Dr. J. W. D. Bull**): Cholecystitis is a disease of the gall-bladder, that is, of the walls of the gall-bladder. The gall-bladder and the bile are made up of chemical elements similar to those of the surrounding tissues. X-rays, therefore, do not differentiate them from their neighbours. It has been said that the gall-bladder can often be seen in plain films—perhaps because it contains bile of high calcium content. However this may be, it has been my misfortune that whenever I have identified the gall-bladder in the preliminary radiograph, the cholecystographs later showed that it was in an entirely different place!

When the gall-bladder contains some substance which in its composition has enough of an element of high atomic weight, that element opposes the passage of X-rays more than do the surrounding tissues, and so a shadow is produced on a film, just as it is by a barium meal. There are three occasions when this happens: (1) When there is a gall-stone containing calcium; (2) When the walls of the gall-bladder are calcified: the so-called porcelain gall-bladder; (3) Cholecystography.

Cholecystography is the adaptation of Rowntree and Abel's discovery that phenolphthalein was extracted from the blood by the liver and excreted in the bile.

The use of halogen compound, a derivative of phenolphthalein, was introduced by Graham and Cole in 1924, and the term Graham's test is often used as being synonymous with cholecystography. The tetra-chloro and the tetra-bromo derivatives were soon discarded in favour of the corresponding iodine compound, the di-sodium salt of tetra-

iodophenolphthalein, now known as iodophthalein B.P. Its isomeride sodium phenol tetra-iodophthalein has not been manufactured in this country and it has scarcely been used here. Recently, an entirely new contrast medium, hydroxy-iodophenyl-phenyl-propionic acid, has been produced. The Medical Research Council in 1942 announced that the name of Pheniodol B.P. had been adopted for this compound, originally manufactured abroad. It is taken by mouth only. It disturbs the patient less than the phthalein compounds. The density of the shadow and the results are usually as good as those following the intravenous injection of iodophthalein. No better results have been obtained by the more complicated routines, often used because of the relative inefficiency of the so-called "dyes" when taken by mouth. It is usual to give the compound at night, and to make the examination next morning, the patient fasting.

The results of cholecystography can be divided into three groups:

(1) When the gall-bladder fills with and concentrates the opaque medium, contains no gall-stone or adenoma, &c., and contracts down after a fatty meal, it is radiologically normal.

(2) Though otherwise radiologically normal, it may empty slowly, whether it contracts or not. Even twenty-four hours after the fatty meal, much opaque material is often seen. Since using pheniodol, one has noticed this delayed emptying more frequently, possibly because of the greater density of the shadow. The gall-bladder is seen often, though not always, to shrink in size when gall-stones are present; even though afterwards the pathological report reads that the walls are thickened and fibrosed.

Does the emptying rate, and perhaps also the contractibility, mean more than the rapid or slow emptying rate of the otherwise normal stomach. Like the latter, it may vary in speed in the same person at different examinations. Is it more than a visible manifestation of an inward and mental state? a psychosomatic condition? In discussing the emptying rate and the contractibility of the gall-bladder, it seems curious that no reference is ever made to the possibility that the liver has made some more bile, and that this is entering and filling the gall-bladder.

(3) When the gall-bladder *fails* to fill with and to concentrate the opaque medium, four things may have happened:

(a) The medium may never have been extracted from the blood: so much of the liver must be destroyed before bile is no longer excreted, that in the clinical picture, attention is not likely to be focused on the gall-bladder.

(b) The medium, like the bile, may never have been able to leave the liver, or at any rate to reach the common bile duct and jaundice results. As a general rule, cholecystography is obviously contra-indicated in jaundice, though if carried out in some cases of infective hepatitis, a poor filling of a small gall-bladder may be seen. Again, clinically, it is the liver and not the gall-bladder that beckons.

(c) The iodine-containing bile may have been prevented from reaching the gall-bladder: in most cases by a calculus in the neck or the cystic duct itself, but adhesions, perhaps from a duodenal ulcer, or other causes may obstruct the duct to such an extent that "no filling" is reported, even though the gall-bladder itself is normal.

(d) Finally the mucous membrane of the gall-bladder may have lost its power to concentrate the bile, whether gall-stones are present or not, as in true cholecystitis.

A sub-division of this group is that in which the density of the shadow is less than normal—? a temporary or permanent but partial loss of function by the mucous membrane. The density may sometimes be greater, or less, at a second examination after a period of medical treatment. These are the cases which are so difficult to assess. If the shadow is below the average, has the mucous membrane partially lost its power to concentrate: (1) Because of a non-opaque calculus or other block which produces a partial stoppage and so a reduced entry of bile to the gall-bladder; (2) because the gall-bladder is unusually large and the same amount of opaque material spread over a broad area produces a lesser density; (3) because of inflammatory changes in the wall; (4) because of a temporary vasomotor or similar disturbance.

It would seem that radiologically one can only comment on this unsatisfactory group and leave the further analysis to the clinician.

The fallacies are: (1) Congenital anomalies.

Birds, fish, rodents, the horse, deer, camels, the rhinoceros and the elephant are said normally not to possess a gall-bladder. To Morgagni is given the credit of being the first

to report its *absence* in the human. Knox, Mentzer, Schaeffer and Hirschbaum report in all on about 10,000 autopsies and found only 5 cases where the gall-bladder was congenitally absent. *Rudimentary* gall-bladders are equally rare. In one series of 10,000 examinations, 5 cases of *double* gall-bladder are reported. When two are present, disease may affect only the one.

These are obviously all very rare findings. When there are symptoms suggesting disease of the gall-bladder, the risk that congenital anomalies are producing misleading cholecystographs is extremely small.

(2) A gall-bladder which has failed to fill with and to concentrate the opaque medium may have done so because, so to speak, it is no longer there; cholecystography has been requested often after cholecystectomy. It is obviously impossible to fill a gall-bladder which has been removed! To request "cholecystography" because it is not certain whether the gall-bladder was removed, or whether it was only drained, and has perhaps recovered its function, is another matter.

(3) Improper preparation and poor radiographic technique can, and often do, mislead. It may be that the patient misunderstood the instructions or even that he has wilfully failed to take the iodophthalein or the pheniodol by mouth. The intravenous injection, providing it is intravenous, a painful and sad incident if it is not, will avoid this. The patient may have taken a large breakfast of bacon and eggs and so emptied his gall-bladder before the examination is made! A far more common cause of faulty interpretations is due to unsatisfactory technique: either the wrong dosage of the opaque medium, movement during the exposure, incorrect positioning or unsuitable radiographic factors. These can often be assessed, and if apparatus and electrical conditions are suitable, can be improved at a second examination. Overlying gas shadows are frequently a nuisance. Good technique will in most cases enable one to project them away from the gall-bladder. The same thing applies to the unabsorbed iodophthalein when taken by the oral route, but scarcely ever by the intravenous route or with pheniodol.

No reference has been made to cholesterosis or the strawberry gall-bladder. This is because I have not been able to convince myself that there are *any* radiological signs of its presence.

No attempt has been made to give statistics. It is found when inquiry is made afterwards, that in only a small proportion of abnormal cholecystographs is there a histological report or even a surgical finding! Figures therefore would be of no value. Clinicians who see the cases can perhaps speak with greater authority from their own experience.

To sum up:

(1) The gall-bladder may be radiologically normal in appearance and function. When the examination has been made *properly*, in what percentage of cases do the clinical, the surgical, and eventually the therapeutic findings, disagree with the radiological report?

(2) Proper technique having been used, when a gall-bladder fails to fill with and to concentrate the opaque medium, a pathological condition is practically always present, not necessarily in the gall-bladder, or its duct, though usually so. Since radiologically it is not possible to say whether the disease is outside the gall-bladder, due to one or more non-opaque gall-stones or to cholecystitis, there is obviously no direct radiological sign of cholecystitis.

(3) When there is only a poor filling and no gall-stones can be seen, care is needed. The clinical evidence must be very definite, otherwise it is better to check by a second examination; after an interval.

(4) The emptying rate of the gall-bladder varies. Has this any significance in the diagnosis of cholecystitis, or even in the diagnosis of any actual lesion?

Mr. A. J. Gardham: *Chronic cholecystitis without stones.*—Cases with a presumptive diagnosis of chronic cholecystitis without stones may be divided into two groups: (1) Those in whom disease of the biliary system is indicated by jaundice, and (2) those in whom it has been diagnosed on less certain grounds.

In Group 2 the clinical picture as I meet it is fairly typical; the patient is generally a woman, often of the type and habit traditionally associated with gall-stones and she

complains of pain which is variable in intensity; never of the severity of a true biliary colic and is situated, vaguely, in the right upper abdomen. She has no physical signs and brings with her X-ray plates which show either a normal gall-bladder, or one which concentrates poorly, or perhaps one which fails altogether to show on cholecystography. If the gall-bladder fails to show altogether I generally take it that I am dealing with a cystic duct which is blocked by a stone which is not visible on X-ray examination. My radiological colleague has referred to the possibility of the mucosa losing its power of concentration to such an extent that the gall-bladder fails to show altogether on cholecystography, even when there are no stones present. The only circumstances in which I have seen such cases are when gall-stones have been present and have escaped, either by means of a fistula, or by the normal passages; and provided that I am assured of the technical efficiency of the X-ray examination, I am prepared to take the evidence that there is no shadow on cholecystography to mean that a stone is or has been present.

The group of cases in which, on X-ray examination, the function is diminished or unimpaired makes a very different story. My experience of surgery in these cases is both limited and discouraging. I have removed a few such gall-bladders, always at the request of a physician; some of them have been normal to external examination, others have looked thick and inflamed. Sometimes the mucosa has been normal, sometimes it has been thick and sometimes it has been actually studded with cholesterin. The only thing which these cases have in common is that I have always regretted operating on them because the improvement in their health does not seem to me to be sufficient to compensate for the discomforts and risks of what is, after all, a major operation.

The only justification which I can see for operation in cases of this sort is that a timely operation for the removal of a gall-bladder which is not yet grossly diseased may prevent the formation of gall-stones and avoid the invalidism which results from the presence of stones in patients who are no longer in a fit condition to stand the operation of cholecystectomy. My impression is, although I cannot confirm it by statistics, that the patients who suffer from the symptoms generally attributed to cholecystitis without stones are of a younger age-group than those who come up with frank cholelithiasis.

If the theory of infection as a primary cause for gall-stones is correct, all the cases of frank gall-stones that we see must have a precalculus stage of cholecystitis lasting for years; yet in the majority of cases neither they nor their doctors have thought the symptoms sufficiently bothersome to merit the attention of a surgeon. So if a gall-bladder at this stage requires operation it is on the grounds of prognosis and not of symptoms. It is also worth while remembering that an inflammation of the gall-bladder, severe enough to lead to perforation into the duodenum, may be practically symptomless. I myself have seen two cases in which a fistula between the gall-bladder and the duodenum was discovered accidentally at an X-ray examination and I believe that it is the exception in cases of gall-stone obstruction of the small intestine to obtain a history of any symptoms suggestive of a severe and long-continued inflammation of the gall-bladder. Consideration of these facts leads me to the belief that cholecystitis without stones is not a good explanation for abdominal symptoms and that such symptoms are unlikely to be relieved by removal of a non-calculous gall-bladder. Even if the theory that gall-stones are infective in nature is not correct and that it is a metabolic error which leads to formation of the stones, it seems most unlikely that the gall-bladder could be the only organ affected by the metabolic change, and if it only shares with many other organs the effects of this change, the excuse for its extirpation unless stones are actually present and giving rise to symptoms is even slighter.

We may now consider the cases which present with a history of jaundice. These, in some ways, are more difficult because we know that disease of the biliary system is present. Most frequently the story is that of a case with an undoubted history of biliary colic and jaundice, without X-ray evidence of stones. I see quite a number of these cases, and I generally allow the patient to have two attacks before I advise operation. Operating on these indications I have found gall-bladders which are apparently normal, and when opened contain no stones, but I have also found gall-bladders which to external examination were normal, but on opening showed one or more tiny stones, ready to pass into the common duct. It is not at all easy for a surgeon to decide what action he will take in these circumstances. The easy thing for him to say is that however normal the gall-bladder looks, it may contain or at least have contained stones and that it should be removed. Unfortunately all surgeons know that a proportion of these cases continue to have similar attacks after removal of the gall-bladder, and they are a source of great anxiety to surgeons, because the question always arises of whether the operator may

possibly have overlooked a stone in the common duct. The problem before the surgeon is whether there is such a condition as dyskinesia of the biliary passages where owing to a failure of relaxation of the sphincter of Oddi the pressure in the common bile duct rises to the point where pain is produced, without there being any organic obstruction. Such a condition exists in the ureter and can be seen by cystoscopy, and is called cystic dilatation of the ureteric orifice. There is a considerable probability that some analogous condition does occur in the biliary passages, although we cannot see the ampulla of Vater, and personally I think it does, although it is rare. In any case the condition is one which merits the very serious attention of a surgeon who is dealing with a case where the history is that of attacks of biliary colic with jaundice and no stone can be demonstrated. The treatment of these cases is a technical surgical problem and I think it would be out of place to discuss it here; perhaps it can be summed up most adequately by saying that the more one has considered these possibilities, the less ready one is to remove a gall-bladder which is not obviously diseased.

Before concluding, I think it would be appropriate to mention the possibilities of peritoneoscopy. The gall-bladder is an organ which is almost visible on peritoneoscopy, unless it is abnormal and buried in adhesions, and although a normal appearance of the gall-bladder does not always exclude the possibility of calculi it may answer the question of whether an operation is necessary. I have found peritoneoscopy particularly useful in a type of case which seems to have become more frequent recently; that is a patient with very severe and persistent jaundice which had at first been regarded as an infective hepatitis, but has finally worn down the confidence of the physician to such an extent that he has called in the surgeon because he thinks he may be dealing with a stone in the common bile duct which is showing abnormal symptoms. Laparotomy in such cases is a very serious matter, and it may be possible by peritoneoscopy to establish that the gall-bladder is neither distended as it would be if there were a growth obstructing the common bile duct, nor inflamed as it would be if there were an obstruction caused by a stone. If, in fact, a normal gall-bladder can be seen in combination with a liver which is moderately enlarged and shows a greenish slaty appearance, it is fairly safe to say that the case is one of infective hepatitis.

A discussion followed in which the undermentioned took part: Professor B. Kopan, Dr. C. H. Atkinson, Professor B. O. C. Pribram, Dr. E. R. Cullinan, Dr. D. Gillespie.

The Influence of Medical Poets on English Poetry

PRESIDENT'S ADDRESS

By Sir ARTHUR MACNALT, K.C.B., M.D.

This paper will be published in full in the June issue of the *Poetry Review*, the journal of the Poetry Society Incorporated.

[April 3, 1946]

Male Eunuchism Considered in the Light of the Historical Method

By A. P. CAWADIAS, O.B.E., M.D.

THE natural history of diseases, which is the science of medicine, is usually described by means of the didactic method, which consists in giving all the facts and conceptions accepted at the time of publication about the four chapters of this natural history, i.e. the ætiological, the symptomatological, the physiopathological and the therapeutic. This didactic method, although good as a rough guide in everyday practice, is insufficient for intimate understanding of the particular disease, and provides no basis for future research. Thus it cannot be termed absolutely scientific. It needs to be completed, and in fact preceded by the historical method, which consists in studying step by step the development of medical research, thought, and practice referring to the four chapters of the natural history of diseases. Only the historical method enables us to understand the particular malady and gives us scope for future research and development. In all sciences, in physics, in chemistry, in mathematics, the historical method is applied as the highest scientific method. Science without history of scientific thought is inconceivable.

Probably in no other branch of medicine is the importance of the historical method so great as in endocrinology. The study of eunuchism through this method which I now present will, I think, contribute to a better understanding of this disease. History of medicine is not an occupation for purely scholarly or dilettante minds but in its more important aspect, that dealing with the development of medical thought, is the highest scientific method in medicine. Those who cultivate it obtain a more thorough understanding of medical problems and thus a greater certitude and style in their practice.

THE ÆTIOLOGICAL CHAPTER: HOW EUNUCHISM ARISES

Eunuchism means male castration. The term arises from two Greek words meaning "bed" and "guarding" and indicates the principal function of male castrates in ancient times. The ancient Greeks used also a term meaning "cut", which in its Latinized form "spado" was used by the Romans.

Eunuchs were employed by ancient Eastern peoples such as the Assyrians, the Babylonians, the Chinese and some African peoples as special slaves or servants. Their asexuality, which, however, was not always complete, fitted them for employment as guardians and servants in harems. They were placed also in other confidential posts because, as a passage in Xenophon's *Cyropædia* indicates, being distinct from the rest

of mankind they could not be distracted by sexual considerations and adventures and would be more firmly attached to the person of their master. Such slaves were procured from prisoners of war, whom their victors castrated as a symbol of complete subjugation. This war castration was much in vogue among pre-Hellenic barbarians, as shown by ancient sculptures and paintings such as those of Karnak. Later, parents used to castrate their children so as to obtain for them a post and livelihood in the leading families. Castration for this purpose, a distinct manifestation of Eastern barbarism, was unknown among the ancient Greeks, and also among the Romans as long as they were under the influence of Greek civilization. In Imperial Rome, however, after Rome had come into contact with the Orient, eunuchs were introduced into the city, and as Gibbon writes: "The eunuchs who in the time of Augustus had been abhorrent as the monstrous retinue of the Egyptian Queen, were gradually admitted into the families of matrons and senators and of the emperors themselves." They exerted a certain rôle. Claudius heaped riches and rewards on his freedman eunuch Posides, who employed his wealth in building. Hence Juvenal's verse "*Ut spado vincebat Capitolia nostra Posides*". Such was the influence of eunuchs that in A.D. 240 the great statesman Misithenes, father-in-law of the Emperor Gordian, started his otherwise temporary reform of the Empire by expelling them from the palace. The Roman emperors took eunuchs with them into Constantinople, where they became so influential as often to dominate the Imperial court. Some of them did good work, as for example Narses, the famous general of Justinian. However, when the Byzantine court became more Hellenized the eunuchs disappeared. The slave-eunuchs of the ancient Eastern peoples disappeared later. The Turks retained such eunuchs until the fall of Abdul Hamid. In Egypt the production of eunuchs ceased with British occupation and following a convention between Great Britain and Egypt in 1877. The end of Imperial China was the end also of Chinese eunuchs. I have no precise data on Abyssinian eunuchs, although I believe that Haile Selassie succeeded in stopping that barbaric custom.

Religious eunuchs form a second class. A mystical madness led priests and followers of certain ancient Eastern religions to castrate themselves so as to devote the whole of their being to the service of their divinities. Most servitors of the cult of Cybele were castrates, and the Roman Emperor Heliogabalus is said to have subjected himself to that mutilation in order to become the chief priest of Cybele. The Jews did not of course accept castration. We read in Deuteronomy XXXIII, i: "He that is wounded in the stones or has his privy member cut off shall not enter into the congregation of the Lord." Early Christians, however, swayed by the same mystical madness as the heathens, considered that in order to devote themselves utterly to God they should remove all sexual temptations, and in some cases castrated themselves. They were seconded in that decision by a misinterpretation of certain passages in the New Testament referring to sexual sin in general. The great Origen was a castrate. Many patriarchs of Constantinople were castrates. The Valerians in the third century also castrated themselves for religious reasons. This barbaric procedure became so prevalent in the clergy that the Council of Nicea (A.D. 325) promulgated that those who had castrated themselves voluntarily were debarred from priestly offices, the interdiction not applying, however, to persons castrated for medical reasons nor to those who had been castrated against their will by barbarians.

Religious castration was renewed in the middle of the eighteenth century by a sect originating in Russia and spreading later into Rumania, known as Skoptzy. The mystical madness of these fanatics is evident in their ceremonies of initiation, in which the initiate was brought to a state of Dionysiac frenzy and then castrated. It is shown also in their intensive proselytism. The sect was persecuted by the Russian police but found greater freedom in Rumania. They existed there at all events before this war and were mostly coachmen or drivers in Bucharest and other towns. Their precise number was unknown because they were very secretive, but there were whole villages of Skoptzy. From the medical point of view they are famous. They were the first eunuchs to undergo full medical study, first by Pelikan, then with precise methods by Eugène Pittard and later by Tandler and Grosz and by Koch. Our medical knowledge of eunuchism is based on study of the Skoptzy.

The third class of eunuchs is formed by singer eunuchs. Castration arrests the development of the male larynx and thus allows these males to keep the sweet infantile-feminine soprano voice. Castrates were much sought as singers, particularly for churches, and the Sistine Chapel choir was renowned for its "castrati". Parents in Italy, where that custom originated, had their children castrated when they wished them to have a singer's career, and according to Hirschfeld the windows of barbers and male nurses in Rome during the eighteenth century often bore the notice "*Qui si castrano ragazzi a buon mercato*". To circumvent the interdiction of the Council of Nicea these eunuchs were considered

as castrated for medical reasons. The voices of these castrates were beautiful, and in 1877 Rossini wrote the opera "Aureliano in Palmyra" for the castrate Velutti. The custom was abolished only at the advent of Leo IX. Thus even a few years ago singer eunuchs could be encountered in Italy, as testified by Hirschfeld.

The fourth class of eunuchs comprises victims of criminal assault, of whom the most famous is the philosopher Abélard, who was attacked and castrated at the instigation of Canon Fulbert, the uncle of the seduced Héloïse. Prisoners of war forced to undergo castration belong to this category, as do the numerous castrates made by the Germans recently under the cloak of eugenics.

Finally, we have eunuchs castrated for medical or eugenic reasons. Our ancestors were somewhat lavish with this procedure. Castration was prescribed as a preventive for hernia, for certain skin diseases, and for leprosy. Ambroise Paré protested against these excesses. Nowadays medical castration is practised only on the basis of more precise indications. Eugenic castration has been abolished in favour of the less destructive ligation of the spermatic cord.

THE CLINICAL DESCRIPTIVE CHAPTER

Although eunuchs have existed since remote antiquity, a medical description of the picture presented by human castration is not found until the later nineteenth century, probably because eunuchism was not until then considered as a medical problem.

The first period of the medical study of eunuchism is dominated by the work of Goddard and of Pelikan. Even in their work the sociological and anthropological aspects overshadow clinical study. Ernest Goddard (1827-1862), a French anatomist and anthropologist, studied eunuchs during his travels in Egypt. E. W. Pelikan (1824-1884), a great authority on forensic medicine in Russia and president of the Imperial Public Health Council, studied Skoptzys. Both these authors described vaguely the macrosomia and macroskelia of eunuchs, the variations in their adiposity and their general behaviour. On the same lines Eugène Matignon, a French physician at the court of Pekin, studied the eunuchs of the Chinese Imperial Palace (1906). Some isolated studies of the skeletons of eunuchs such as that of Maiticjewski (cited by Pelikan) and of Ecker add very little. In fact all this work is only an introduction to the study of eunuchism because a precise method of exploration was lacking.

The second period, which began with the twentieth century and ended with the first world war, is one of precise anthropological research and of dawning medical study. It is dominated by Eugène Pittard, who studied principally the Skoptzys with an excellent anthropological technique made of precise mensurations and comparisons on large scales. The anthropological point of view veers more to the medical-morphological. Stimulated by this anthropological work, and principally by experimental work on animal castration, clinicians took deep interest in the whole question. Launois and Roy in 1904 and Möbius in 1906 produced the first medical studies of the morphological and psychological syndromes of eunuchs. During this period the sociological-anthropological lines of the Goddard-Pelikan era were followed by R. Millant, a young French physician killed in the first world war, and by Zambaco Pachah, a Greek physician who became personal physician to Abdul Hamid and studied the eunuchs of Constantinople. The descriptive work of Tandler and Grosz and of W. C. Koch, who studied the Skoptzys during the German occupation of Rumania, closes this period. These Austrian and German authors followed the lines of Pittard but contribute only to clarification of certain morphological details. The work of Pittard and others has demonstrated the different manifestations according to whether the castration has occurred before or after puberty. The morphological syndrome has been well studied. In pre-puberal castrates tallness with macroskelia has been emphasized. Obesity occurs principally in post-puberal castrates late after castration.

The third or contemporary period is essentially medical. Eunuchism is now regarded as an endocrine disease. This change of view and the intensity of the medical work is bound up with the triumphant development of the newest of all branches of medicine, endocrinology. We have taken from R. Martin, Ernest Pittard, Manouvrier and other anthropologists their special measurements for use, often with exaggeration, in our clinical work. However, the morphological point of view, although given undue stress by da Giovanni, Viola, Brugsch and G. Draper, is far from dominating our work. Eunuchism is studied from the point of view of its effects on all organs and systems, on psychology and behaviour, but to-day principally as regards its effects on the biochemical processes of the body, on metabolism, because metabolic disturbances are the key to therapeutic handling as they link clinical description with physiopathology.

During this third or "medical" phase the symptomatology of eunuchism has been

of mankind they could not be distracted by sexual considerations and adventures and would be more firmly attached to the person of their master. Such slaves were procured from prisoners of war, whom their victors castrated as a symbol of complete subjugation. This war castration was much in vogue among pre-Hellenic barbarians, as shown by ancient sculptures and paintings such as those of Karnak. Later, parents used to castrate their children so as to obtain for them a post and livelihood in the leading families. Castration for this purpose, a distinct manifestation of Eastern barbarism, was unknown among the ancient Greeks, and also among the Romans as long as they were under the influence of Greek civilization. In Imperial Rome, however, after Rome had come into contact with the Orient, eunuchs were introduced into the city, and as Gibbon writes: "The eunuchs who in the time of Augustus had been abhorrent as the monstrous retinue of the Egyptian Queen, were gradually admitted into the families of matrons and senators and of the emperors themselves." They exerted a certain rôle. Claudius heaped riches and rewards on his freedman eunuch Posides, who employed his wealth in building. Hence Juvenal's verse "*Ut spado vincebat Capitolia nostra Posides*". Such was the influence of eunuchs that in A.D. 240 the great statesman Misithenes, father-in-law of the Emperor Gordian, started his otherwise temporary reform of the Empire by expelling them from the palace. The Roman emperors took eunuchs with them into Constantinople, where they became so influential as often to dominate the Imperial court. Some of them did good work, as for example Narses, the famous general of Justinian. However, when the Byzantine court became more Hellenized the eunuchs disappeared. The slave-eunuchs of the ancient Eastern peoples disappeared later. The Turks retained such eunuchs until the fall of Abdul Hamid. In Egypt the production of eunuchs ceased with British occupation and following a convention between Great Britain and Egypt in 1877. The end of Imperial China was the end also of Chinese eunuchs. I have no precise data on Abyssinian eunuchs, although I believe that Haile Selassie succeeded in stopping that barbaric custom.

Religious eunuchs form a second class. A mystical madness led priests and followers of certain ancient Eastern religions to castrate themselves so as to devote the whole of their being to the service of their divinities. Most servitors of the cult of Cybele were castrates, and the Roman Emperor Heliogabalus is said to have subjected himself to that mutilation in order to become the chief priest of Cybele. The Jews did not of course accept castration. We read in Deuteronomy XXXIII, 1: "He that is wounded in the stones or has his privy member cut off shall not enter into the congregation of the Lord." Early Christians, however, swayed by the same mystical madness as the heathens, considered that in order to devote themselves utterly to God they should remove all sexual temptations, and in some cases castrated themselves. They were seconded in that decision by a misinterpretation of certain passages in the New Testament referring to sexual sin in general. The great Origen was a castrate. Many patriarchs of Constantinople were castrates. The Valerians in the third century also castrated themselves for religious reasons. This barbaric procedure became so prevalent in the clergy that the Council of Nicea (A.D. 325) promulgated that those who had castrated themselves voluntarily were debarred from priestly offices, the interdiction not applying, however, to persons castrated for medical reasons nor to those who had been castrated against their will by barbarians.

Religious castration was renewed in the middle of the eighteenth century by a sect originating in Russia and spreading later into Rumania, known as Skoptzy. The mystical madness of these fanatics is evident in their ceremonies of initiation, in which the initiate was brought to a state of Dionysiac frenzy and then castrated. It is shown also in their intensive proselytism. The sect was persecuted by the Russian police but found greater freedom in Rumania. They existed there at all events before this war and were mostly coachmen or drivers in Bucharest and other towns. Their precise number was unknown because they were very secretive, but there were whole villages of Skoptzys. From the medical point of view they are famous. They were the first eunuchs to undergo full medical study, first by Pelikan, then with precise methods by Eugène Pittard and later by Tandler and Grosz and by Koch. Our medical knowledge of eunuchism is based on study of the Skoptzys.

The third class of eunuchs is formed by singer eunuchs. Castration arrests the development of the male larynx and thus allows these males to keep the sweet infantile-feminine soprano voice. Castrates were much sought as singers, particularly for churches, and the Sistine Chapel choir was renowned for its "castrati". Parents in Italy, where that custom originated, had their children castrated when they wished them to have a singer's career, and according to Hirschfeld the windows of barbers and male nurses in Rome during the eighteenth century often bore the notice "*Qui si castrano ragazzi a buon mercato*". To circumvent the interdiction of the Council of Nicea these eunuchs were considered

until to-day and probably for ever the basis of physiopathological thought and research. The endocrinological work of John Hunter is scattered in all his work. The most important part was collected in 1787.

John Hunter performed castration and transplantation of gonads. Reasoning from his experiments in the light of comparative physiology and clinical observation he showed the influence of the testis on primary and secondary sexual characters, of which he was the first to give an accurate conception. He went further. He transplanted the small rudimentary spurs of a hen to a cock, and they grew like male spurs. He demonstrated thus that X force which emanates from the testis to give the animal its male characters. Sixty years later Arnold Berthold, a Göttingen physiologist, repeated Hunter's experiments, confirmed the effects of castration and confirmed more definitely the inhibition of these effects by transplantation of testis in castrate birds. He confirmed the X influence of the testis on male sexual characters and, reverting to the ideas of Thomas Willis and of Théophile de Bordeu, he postulated that the X force should be a substance entering the blood from the testis. Without wishing to belittle the work of Berthold I cannot help protesting against the opinion of German authors, unfortunately propagated even among other nations by subtle German propaganda, that Berthold is the founder of experimental endocrinology and the originator of the doctrine of internal secretions. The conception of internal secretions is found in the writings of Willis, of Brugsch and of Bordeu. The experimental proof was given first by John Hunter, who is thus the founder of experimental endocrinology whose brilliant development we are witnessing to-day. That Berthold knows the work of John Hunter and other British scientists cannot be doubted, for the University of Göttingen and Hanoverian physicians as a whole were in close touch with British thought. Charles Zimmermann (1728-1795), physician to the King in Hanover, was always saying: "I write in German but think in English." His successor Wichmann translated British medical authors into German and modelled his thought and practice on these authors.

The conception of the internal secretion of the testis and thus the physiopathology of eunuchism, foreshadowed in the theories of Willis and Bordeu and the experiments of John Hunter and Berthold, were definitely established by the experiments of Pézard and of Goodale from 1911 onwards. The long lapse of time before the fructification of the John Hunter-Berthold experimental work may seem astonishing, but was necessary for establishment of the general conception of the internal secretions by Claude Bernard, Addison and Brown-Séquard in the early fifties. Experimentation, like clinical findings, can fructify only when there is a general conception to direct their interpretation. History of medicine gives the lie to those "men of common sense" who want "facts not theories." The progress of science needs theories, as Henri Poincaré so brilliantly developed in his *La Science et l'Hypothèse*. Pézard and Goodale developed all details of the action of the testis on the primary and secondary sexual characters.

Later the Steinach group of Vienna completed the work of the French, American and British experimenters. Some of these experiments, such as, for instance, those on intersexualization, are very ingenious, but on the whole this group developed only details. Their interpretations went a little further than was warranted by their experimental work. A further demonstration that experimentation when not assessed in the light of clinical observation and comparative physiology (the Hunterian Tripod) is not always safe.

After the Pézard-Goodale era comes the last phase, which gives precision, to the physiopathology of eunuchism and directs treatment. It is the era of testicular hormone research. As early as June 1, 1889—a momentous date in the history of endocrinology—Brown-Séquard described at the famous meeting of the Société de Biologie in Paris the extraction of the testicular hormone through a saline solution. The idea was right, the experiment fallacious, and for many years the hormone evaded extraction. Then in 1913 Henri Iscovescu, a Rumanian working in the laboratory of Dastre at the Sorbonne, produced a more active lipid extract. Further research lagged, because chemical methods had to be perfected and a biological test evolved. This was obtained, and enabled F. C. Koch to begin his great work thirteen years later, in 1926. First with McGee and later with Gallagher, Koch—who with the modesty characteristic of great scientists put the names of his junior collaborators before his own in all his papers—produced at Chicago the first real purified testicular hormone. But extraction was difficult because tons of bull testis were required for a small yield. Nearly ten years after the first work of Koch, in 1935, Ernest Laqueur of Amsterdam and his group obtained Koch's extract from bull testis in crystalline form. Taking as their basis the work of the Göttingen chemist Adolf Butenandt, who had isolated from male urine an androgen similar up to a certain point to Koch's extract (in fact, the excretory product of Koch's extract) and determined its chemical formula, the Dutch chemists determined the chemical formula

completed, and the following data have been found to constitute the clinical syndrome of male eunuchism.

In pre-puberal castration, (1) Tallness, macroskelia, under-development of hair on face and body with good development of scalp hair, thinness. Obesity develops much later in some cases from postpituitary reaction. (2) Absence of potency and libido, hypoplasia of external genitals, prostate and seminal vesicles. (3) Variable psychological picture according to the reaction of the psyche. Usually tendency to introversion with infantilistic traits and abnormalities of behaviour of "limelight" nature due to over-compensation of an inferiority complex. Pre-puberal castrates, however, often show normal intellectual functions and capacity for action and achievement. (4) Diminution of basal metabolism, disturbances (not clearly determined) of creatine metabolism, slight diminution in the excretion of androgens and oestrogens in the urine.

In post-puberal castrates, (1) No tallness, no macroskelia, usually no under-development of hair (Pittard's hairy castrates), obesity of special girdle type setting in earlier. (2) Potency and libido can be maintained. (3) Same psychological manifestations as in pre-puberal castrates, but coloured by the personality structure of the patient and by the environment. Similar metabolic and hormonal findings.

That much remains to be done from the clinical point of view is shown by the following words of J. P. Pratt in the last edition (1939) of Allen's "Sex and Internal Secretions". "In modern literature emphasis on the subjective symptoms following castration still prevails. Good observations of the objective symptoms are rare ... the effects of loss of these organs (the testes) in the adult remain controversial."

THE PHYSIOPATHOLOGICAL CHAPTER

Clinical medicine has undergone a complete revolution in the last forty years. Our ancestors advised leaving their theories on disease (meaning the pathogenic or physiopathological conceptions) with their overcoats on entering the clinical ward. Thus the clinician had to limit himself to a thorough examination, a good differential diagnosis, and the application of any medicine shown by purely empirical observation to be effective in the disease he had diagnosed. To-day, on the contrary, after our differential diagnosis we have to ask ourselves: "What is really happening in this patient? In what manner is his physiology disturbed?" The answer enables us to apply effective treatment, but for that we have to bring our physiopathological knowledge to the bedside. This knowledge is of course more precise than the pathogenic speculations of our ancestors. It is based on experimentation and has been controlled by clinical results. Even so, physiopathological reasoning is difficult and may be dangerous. It is necessary, however, unless we wish to remain in the therapeutic nihilism of the nineteenth century. To be a good clinician in the modern sense of the term does not mean merely to have qualities of observation adequate for a good differential diagnosis, but means also to have physiopathological, mainly biochemical, knowledge and the power of accurate reasoning so as to determine what is wrong in the physiology of the individual patient.

It is thus important to examine step by step the answer to the problem, What is happening to the organism of the eunuch? Through what mechanism does removal of the testis give rise to the clinical picture delineated by descriptive anthropologists and clinicians?

The ancient Greek physicians had no answer to that question. They limited themselves to accepting, in the words of Aretaios, that semen "makes man", makes virility, and thus that lack of semen caused the eunuch to lack virility. This was a descriptive but not a physiopathological statement.

The first answer to that question was given by Thomas Willis in the seventeenth century. He had the first intuition of an internal secretion of the testis. In his *De Cerebri Anatomie* (1664) he writes that the blood receives from the genitals "certain particles imbued with a seminal tincture" which "carried back into the bloody mass make it vigorous and inspire to it a new and lively virtue". Nearly a hundred years later Théophile de Bordeu of Montpellier developed the same idea. "The semen imparts, as is well known, a firm masculine tone to all parts as soon as it can be drawn off and sent into the humours and solids by its natural organs. It sets a new seal on the animalism of the individual, who is in part subject to the action of this creative liquor." And in another passage he writes: "The aura seminalis serves more than the other liquors as a link or intermediary between the body and the mind" (*Œuvres Complètes*, II, 942). Eunuchism resulted from lack of this "creative liquor" from the testis. This was hinted principally by Bordeu.

The idea of an internal secretion of the testis, lack of which would determine eunuchism, was dragged from the domain of speculation by the great work of John Hunter (1728-1793), who is amongst other things the creator of experimental endocrinology. He is even more than that. What Willis and Bordeu thought, John Hunter tried with the method which he introduced into medicine, the combination of clinical observation, comparative physiology and experimentation. The Hunterian tripod was thrust into medicine, to remain

until to-day and probably for ever the basis of physiopathological thought and research. The endocrinological work of John Hunter is scattered in all his work. The most important part was collected in 1787.

John Hunter performed castration and transplantation of gonads. Reasoning from his experiments in the light of comparative physiology and clinical observation he showed the influence of the testis on primary and secondary sexual characters, of which he was the first to give an accurate conception. He went further. He transplanted the small rudimentary spurs of a hen to a cock, and they grew like male spurs. He demonstrated thus that X force which emanates from the testis to give the animal its male characters. Sixty years later Arnold Berthold, a Göttingen physiologist, repeated Hunter's experiments, confirmed the effects of castration and confirmed more definitely the inhibition of these effects by transplantation of testis in castrate birds. He confirmed the X influence of the testis on male sexual characters and, reverting to the ideas of Thomas Willis and of Théophile de Bordeu, he postulated that the X force should be a substance entering the blood from the testis. Without wishing to belittle the work of Berthold I cannot help protesting against the opinion of German authors, unfortunately propagated even among other nations by subtle German propaganda, that Berthold is the founder of experimental endocrinology and the originator of the doctrine of internal secretions. The conception of internal secretions is found in the writings of Willis, of Brugsch and of Bordeu. The experimental proof was given first by John Hunter, who is thus the founder of experimental endocrinology whose brilliant development we are witnessing to-day. That Berthold knows the work of John Hunter and other British scientists cannot be doubted, for the University of Göttingen and Hanoverian physicians as a whole were in close touch with British thought. Charles Zimmermann (1728-1795), physician to the King in Hanover, was always saying: "I write in German but think in English." His successor Wichmann translated British medical authors into German and modelled his thought and practice on these authors.

The conception of the internal secretion of the testis and thus the physiopathology of eunuchism, foreshadowed in the theories of Willis and Bordeu and the experiments of John Hunter and Berthold, were definitely established by the experiments of Pézard and of Goodale from 1911 onwards. The long lapse of time before the fructification of the John Hunter-Berthold experimental work may seem astonishing, but was necessary for establishment of the general conception of the internal secretions by Claude Bernard, Addison and Brown-Séquard in the early fifties. Experimentation, like clinical findings, can fructify only when there is a general conception to direct their interpretation. History of medicine gives the lie to those "men of common sense" who want "facts not theories." The progress of science needs theories, as Henri Poincaré so brilliantly developed in his *La Science et l'Hypothèse*. Pézard and Goodale developed all details of the action of the testis on the primary and secondary sexual characters.

Later the Steinach group of Vienna completed the work of the French, American and British experimenters. Some of these experiments, such as, for instance, those on intersexualization, are very ingenious, but on the whole this group developed only details. Their interpretations went a little further than was warranted by their experimental work. A further demonstration that experimentation when not assessed in the light of clinical observation and comparative physiology (the Hunterian Tripod) is not always safe.

After the Pézard-Goodale era comes the last phase, which gives precision to the physiopathology of eunuchism and directs treatment. It is the era of testicular hormone research. As early as June 1, 1889—a momentous date in the history of endocrinology—Brown-Séquard described at the famous meeting of the Société de Biologie in Paris the extraction of the testicular hormone through a saline solution. The idea was right, the experiment fallacious, and for many years the hormone evaded extraction. Then in 1913 Henri Iscovescu, a Rumanian working in the laboratory of Dastre at the Sorbonne, produced a more active lipid extract. Further research lagged, because chemical methods had to be perfected and a biological test evolved. This was obtained, and enabled F. C. Koch to begin his great work thirteen years later, in 1926. First with McGee and later with Gallagher, Koch—who with the modesty characteristic of great scientists put the names of his junior collaborators before his own in all his papers—produced at Chicago the first real purified testicular hormone. But extraction was difficult because tons of bull testis were required for a small yield. Nearly ten years after the first work of Koch, in 1935, Ernest Laqueur of Amsterdam and his group obtained Koch's extract from bull testis in crystalline form. Taking as their basis the work of the Göttingen chemist Adolf Butenandt, who had isolated from male urine an androgen similar up to a certain point to Koch's extract (in fact, the excretory product of Koch's extract) and determined its chemical formula, the Dutch chemists determined the chemical formula

completed, and the following data have been found to constitute the clinical syndrome of male eunuchism.

In pre-puberal castration, (1) Tallness, macroskelia, under-development of hair on face and body with good development of scalp hair, thinness. Obesity develops much later in some cases from postpituitary reaction. (2) Absence of potency and libido, hypoplasia of external genitals, prostate and seminal vesicles. (3) Variable psychological picture according to the reaction of the psyche. Usually tendency to introversion with infantilistic traits and abnormalities of behaviour of "limelight" nature due to over-compensation of an inferiority complex. Pre-puberal castrates, however, often show normal intellectual functions and capacity for action and achievement. (4) Diminution of basal metabolism, disturbances (not clearly determined) of creatine metabolism, slight diminution in the excretion of androgens and oestrogens in the urine.

In post-puberal castrates, (1) No tallness, no macroskelia, usually no under-development of hair (Pittard's hairy castrates), obesity of special girdle type setting in earlier. (2) Potency and libido can be maintained. (3) Same psychological manifestations as in pre-puberal castrates, but coloured by the personality structure of the patient and by the environment. Similar metabolic and hormonal findings.

That much remains to be done from the clinical point of view is shown by the following words of J. P. Pratt in the last edition (1939) of Allen's "Sex and Internal Secretions". "In modern literature emphasis on the subjective symptoms following castration still prevails. Good observations of the objective symptoms are rare . . . the effects of loss of these organs (the testes) in the adult remain controversial."

THE PHYSIOPATHOLOGICAL CHAPTER

Clinical medicine has undergone a complete revolution in the last forty years. Our ancestors advised leaving their theories on disease (meaning the pathogenic or physiopathological conceptions) with their overcoats on entering the clinical ward. Thus the clinician had to limit himself to a thorough examination, a good differential diagnosis, and the application of any medicine shown by purely empirical observation to be effective in the disease he had diagnosed. To-day, on the contrary, after our differential diagnosis we have to ask ourselves: "What is really happening in this patient? In what manner is his physiology disturbed?" The answer enables us to apply effective treatment, but for that we have to bring our physiopathological knowledge to the bedside. This knowledge is of course more precise than the pathogenic speculations of our ancestors. It is based on experimentation and has been controlled by clinical results. Even so, physiopathological reasoning is difficult and may be dangerous. It is necessary, however, unless we wish to remain in the therapeutic nihilism of the nineteenth century. To be a good clinician in the modern sense of the term does not mean merely to have qualities of observation adequate for a good differential diagnosis, but means also to have physiopathological, mainly biochemical, knowledge and the power of accurate reasoning so as to determine what is wrong in the physiology of the individual patient.

It is thus important to examine step by step the answer to the problem, What is happening to the organism of the eunuch? Through what mechanism does removal of the testis give rise to the clinical picture delineated by descriptive anthropologists and clinicians?

The ancient Greek physicians had no answer to that question. They limited themselves to accepting, in the words of Aretaios, that semen "makes man", makes virility, and thus that lack of semen caused the eunuch to lack virility. This was a descriptive but not a physiopathological statement.

The first answer to that question was given by Thomas Willis in the seventeenth century. He had the first intuition of an internal secretion of the testis. In his *De Cerebri Anatome* (1664) he writes that the blood receives from the genitals "certain particles imbued with a seminal tincture" which "carried back into the bloody mass make it vigorous and inspire to it a new and lively virtue". Nearly a hundred years later Théophile de Bordeu of Montpellier developed the same idea. "The semen imparts, as is well known, a firm masculine tone to all parts as soon as it can be drawn off and sent into the humours and solids by its natural organs. It sets a new seal on the animalism of the individual, who is in part subject to the action of this creative liquor." And in another passage he writes: "The aura seminalis serves more than the other liquors as a link or intermediary between the body and the mind" (*Œuvres Complètes*, II, 942). Eunuchism resulted from lack of this "creative liquor" from the testis. This was hinted principally by Bordeu.

The idea of an internal secretion of the testis, lack of which would determine eunuchism, was dragged from the domain of speculation by the great work of John Hunter (1728-1793), who is amongst other things the creator of experimental endocrinology. He is even more than that. What Willis and Bordeu thought, John Hunter tried with the method which he introduced into medicine, the combination of clinical observation, comparative physiology and experimentation. The Hunterian tripod was thrust into medicine, to remain

The Birth of Modern Endocrinology

INAUGURAL ADDRESS

By Sir WALTER LANGDON-BROWN, M.D.

IN the first place I must congratulate those who have worked so hard for the public recognition of the status of Endocrinology on the success of their efforts, of which the institution of this Section is an outward and visible sign. Next, I would express my deep appreciation of the honour you have done me in electing me your first President. Of recent years I have merely been an interested spectator on the bank of a swiftly flowing and expanding stream of research. Indeed, the only justification for my accepting the distinction you have conferred upon me is that from the onset I have been actively interested in the development of endocrinology. It will, therefore, be fitting that I should devote the greater part of my Address to the history of those early years.

I

Modern endocrinology dates from 1891. A Committee had been appointed to investigate the cause of myxœdema, which was recognized to be associated with the failure of function of the thyroid gland. But the tendency was to regard the disease as due to a failure of excretion, which, indeed, the bloated aspect of the myxœdematous patient might well suggest. Halliburton regarded the accumulation of mucin in the tissues as evidence of this, but it was soon shown that there was a similar infiltration of all the subcutaneous tissues. Victor Horsley was the secretary of this Committee and G. R. Murray, who had worked with him at University College Hospital, suggested that the condition was due not to a failure of excretion but to the loss of an active internal secretion. To emphasize his faith in his hypothesis, he showed a case of myxœdema at a meeting of the Newcastle and Northumberland Medical Society, and said that he proposed to treat it by an extract of thyroid gland. I had the story of what followed from Murray's own lips. A senior member of the Society said that it would be just as sensible to treat a case of locomotor ataxy with an emulsion of spinal cord! Undeterred, Murray made arrangements with a slaughterhouse to be allowed to dissect out sheep's thyroids under antiseptic precautions. The Medical School at Newcastle refused him any facilities, but Armstrong College came to his assistance and gave him a room in which to prepare his extracts. A year later he triumphantly showed the case of myxœdema which had been cured by his extracts before the same Society. When Hector Mackenzie in the following year showed that the extract could be taken in a tablet form, by the mouth, thyroid therapy leapt ahead. Indeed, its early triumphs proved later to be disappointing because it was too hastily assumed that other gland extracts were potent by the same route.

of Koch's extract and named it testosterone. A few months later the Yugoslav chemist Ruzicka, working in Zurich, obtained the hormone synthetically from cholesterol.

The cycle has closed. The visionary "semen" of Aretaios, the speculative "particles imbued with seminal tincture" of Thomas Willis, the X substance of John Hunter and of Berthold, have been thrown into the crucible of the biochemist, who has obtained its intimate construction and is thus able to reproduce this "vital" force from inert substance. . . . The philosopher's stone of the old alchemists has not been an empty dream.

Science, however, never stands still. Work now in progress is leading to discovery of a second testicular hormone, inhibin. Further, we are no longer arrested at the simple formula eunuchism—lack of testicular secretion. Steinach and his group were romancing on the erotization of the cerebral cortex by the sexual hormones, and explained everything in eunuchism, including the mental outlook, by lack of testicular hormones. Their fantasies dragged endocrinology into a period of "glands of destiny," of "glands regulating personality." Glands explained everything, from the conjugal quarrels of a suburban household to the military genius of a Napoleon and the sadistic barbarism of a Hitler. Contemporary work has shown that the endocrine glands and thus the testis are parts to a great system of metabolic or constitutional regulation and correlation. In eunuchism it is not the deficiency of the testis which explains everything, but the reaction of the other elements of this system of constitutional regulation, of the other endocrines, of the nervous vegetative system, of the psyche. The individual variations in eunuchism are explained by the differences of compensation of the other elements of the system of constitutional regulation. For this reason there are eunuchs whom the loss of the testis transforms into pessimistic melancholic individuals, and others who like Narses are capable of resounding military feats. For this reason there are eunuchs incapable of any sexual intercourse and others who maintain their potency.

Thus step by step, from a vague conception of connexion between "semen" and virility, through the conception of lack of testicular internal secretion, we have reached the conception of total disturbance of the system of constitutional regulation, starting with deficiency of the testis but depending on the individual capacity of this system of constitutional regulation.

THE THERAPEUTIC CHAPTER

The therapeutic chapter has developed in parallel. In times when there was no adequate physiopathology of male eunuchism treatment was lacking or was purely empirical. Methods were applied which had been demonstrated by clinical observation to be effective in similar diseases. Far be it from me to belittle the importance of the clinical empirical method in therapy. It is a great method and in the last resort the one at which we shall always end. We cannot limit ourselves to clinical empiricism, however, it cannot be our beginning and our end. True modern therapy consists in the application of therapeutic methods on the basis of physiopathological thinking, but with absolute control of this application by the clinical empirical method.

When physiopathology centred on the lack of testicular hormone, the treatment of eunuchism became endocrinotherapeutic. Hormones were applied, their clinical application, indications, dosage and other details being strictly controlled by the clinical empirical method. The perfecting of hormonal preparations, the introduction of the method of pellet implantation, and the finding of effective oral preparations mark successive steps in progress.

Nowadays, when physiopathology has centred on consideration of total constitutional reactions (real total psychosomatic personality reactions) treatment has become constitutional. Endocrinotherapy remains as a basic procedure, but other general constitutional procedures such as physical methods and psychotherapy are added.

It will be agreed, however, that we have now passed far beyond the birth of modern endocrinology. But one cannot omit reference to the fruitful co-operation of the surgeon, in the treatment of hyperthyroidism, hyperparathyroidism, the adrenogenital syndrome and, more recently, the treatment of myasthenia gravis by thymectomy. However, it will be of interest to review the general biology of the endocrine system in the broadest terms.

II

The enormous energy developed in the zygote provides the impetus which carries the organism on its passage through life. It is perhaps somewhat fanciful but it does remind one of the release of atomic energy. At that moment growth is at its maximum and measured in fractions from that original impetus there is a steady decline in the rate of growth. It has even been asserted that at the moment of birth not more than 2% of that original impetus remains. The organism may be compared to a projectile whose initial velocity constantly diminishes from the moment of its discharge. It does not escape from the second law of thermodynamics, though, as Hopkins shrewdly pointed out, it is the function of life to hold up that dissipating energy at a useful level.

For the last twenty years and more interest has concentrated, however, on the quality rather than on the quantity of growth. The experimental embryological studies, particularly of Roux and of Spemann, revealed amazing facts about the "organizer". At an early stage the graft of embryonic tissue from the dorsal lip of the blastopore is capable of imposing its inherent potentialities on its new environment. As we know, in this way a neural canal is formed on any part of the embryo receiving the implant. Yet at a slightly later stage the implant has to accept the structural development of its host. Clearly specialization of organizing material has already begun. A new interest was aroused by Joseph Needham's demonstration that this "organizer" did not depend on cellular structure; the potent material could be crushed, frozen, or even boiled. Indeed, boiling seemed to set it free and increased the scope of its activities. Therefore it obviously was not a ferment. He found that chemically it was a sterol, reminding us at once of the chemical structure of certain hormones. All this work proves that chemical controls are actively at work before any trace of a nervous system has appeared.

Indeed, it is freely recognized that organisms are controlled by several mechanisms before any semblance of a nervous system has appeared in evolution. Chemotropism may be the most powerful but by no means the only control of this order. It lies too far outside my present topic to give illustrations of stereotropism, heliotropism and so forth; though the subject opens a fascinating vista. We are concerned at this stage with the chemical controls and may regard hormones as a specialized and concentrated form of this. In other words, hormones appeared before the glands which were to house them. Comparative morphology presents a good deal of evidence that many of the recognized endocrine glands had a more primitive function than that which they now possess. Thus in the worms and *Peripatus* there are paired nephridia in every segment. By their means the function to which Claude Bernard attached such fundamental importance, the constancy of the internal medium, is secured. In higher forms of life changes in structure and habitat rendered this method unsuitable. The posterior nephridia were condensed to form the functioning metanephros while some of the more anterior ones became modified to house some of the endocrines. In fact the whole process reminds us of the hermit crab which existed before it found an empty whelk shell for an abode. Thus J. F. Gaskell, continuing his father's researches, showed that in the lamprey there was a wide distribution of adrenalin-secreting cells, though as development increased these became almost entirely confined to the medulla of the adrenal.

Considering the struggle the central nervous system displayed to obtain control of the body it is not likely that it would abdicate in favour of mere chemical controls. The anatomical arrangements of the sympathetic nervous system admirably adapts it to the rapid production of widespread effects. Failure to recognize this was the error into which earlier endocrinologists fell; although the close anatomical association between the nervous and glandular elements of for example the pituitary and adrenal should have prevented this. This close association having once been achieved it was never dropped, showing that it must be of great advantage to the organism. Pathology illustrates this by the observation that in anencephalic monsters the fusion between cortical and medullary portions of the adrenal does not occur.

The intimate nature of the association between chemical and nervous factors was triumphantly demonstrated by the work of Loewi and of Dale. They showed by the

The next phase was the discovery of an active adrenal extract. A good deal of work was being done on tissue extracts in general, which were all found to *lower* blood-pressure. Oliver, a physician practising in Harrogate, declared to Schaefer that he had prepared an extract from the adrenals which *raised* blood-pressure. Somewhat sceptical, Schaefer, nevertheless, invited Oliver to come to University College, London, to work at the subject, and was convinced. Naturally this roused fresh interest in Addison's disease, but strangely enough a failure of excretion on the part of the adrenals, anatomically so close to the kidneys, to detoxicate the body was regarded as the explanation, until Humphry Rolleston in his Goulstonian Lectures for 1895 adduced evidence of its being an "atony" due to the loss of some internal secretion. The isolation of adrenalin soon followed, but as comparative studies showed that adrenalin was purely the production of the medullary portion of the gland we were completely misled as to the real cause of Addison's disease until the work of Stewart and Rogoff. In the same way the real importance of Langley's generalization that the effect of adrenalin on any part was the same as stimulation of the sympathetic nerves to that part was not fully grasped, indeed not until Dale's demonstration of the wide distribution of adrenergic fibres.

Meanwhile Schaefer and Oliver's discovery of an active pituitary extract gave the final blow to the excretory theory of endocrine glands, bringing down with it many then fashionable theories of auto-intoxication. Yet so attractive is the idea to many minds that more than twenty years later it was suggested that hyperparathyroidism was due to a failure to eliminate guanidine.

Bayliss and Starling's discovery of secretin in 1902 was full of theoretical interest but has proved disappointing therapeutically. Taken in conjunction with Pavlov's work on "sham feeding" and "appetite juice" it rather upset the balance of our views as to the relative importance of chemical and nervous factors. Starling was inclined to regard the initial step in digestion as nervous in origin, starting a succession of chemical reactions, the forerunner in each case being necessary to stimulate the next in series. Considering the way in which the nervous system developed increasing control throughout evolution this seemed improbable. Another pointer which was missed for some years was the double nervous and glandular structure of the pituitary and adrenals.

This was the state of affairs when Starling brought forward his hormone theory in his Croonian Lectures for 1905. The name was suggested by W. B. Hardy—meaning a stimulant of chemical origin to act on other structures at a distance. The foundation of a scheme of this sort led to a great increase of interest and research in the whole field of endocrinology. Before long, however, the idea of independent autonomous glands without any central control was modified and that of the integration of the endocrine system began to replace it. This was largely due to increasing recognition of the leading importance of the pituitary gland with its obvious interactions with the other glands. I ventured to call the pituitary gland "the leader of the endocrine orchestra", though later when the importance of the hypothalamus in relation to the pituitary became clearer it seemed more accurate to regard the hypothalamus as holding the still more important rank of conductor of that orchestra.

The search for separate hormones in the pituitary was too amply rewarded, for at least eleven were described! This seemed improbable as the gland only contains three types of cells and there seemed little point in a separate lactogenic hormone which might never be called upon to act throughout the life of the female and never in that of the male. And so the conception arose of the secretions of the cells being modified through the hypothalamus in accordance with the needs of the body. We can, therefore, conceive of a steady autonomous action of the endocrines controlled through the hypothalamus and pituitary as needed.

Meanwhile the clinician was receiving most important aid from the organic chemist. This introduced a much more scientific attitude to the whole subject. One has only to compare Starling's Croonian Lectures with Dodds' Goulstonian Lectures for 1934 to realize the significance of the advance. Here we were shown the importance of a basal group which could be modified to form different hormones and the close relationship between such substances and the stimulators of irregular growth, i.e. the carcinogenetic substances. Perhaps a particularly surprising feature of the work was the demonstration that a synthetically prepared substance of simpler chemical constitution than that prepared by the body could "pick the physiological lock". It may be asked, why should the body go to the trouble of preparing the more elaborate substance? Really the answer is simple. The natural product is formed under strict limitations of temperature, pH and many other physical conditions, whereas the laboratory procedures would be fatal to the cell. The synthetic production of hormones became recognized as possible and very important.

It will be agreed, however, that we have now passed far beyond the birth of modern endocrinology. But one cannot omit reference to the fruitful co-operation of the surgeon, in the treatment of hyperthyroidism, hyperparathyroidism, the adrenogenital syndrome and, more recently, the treatment of myasthenia gravis by thymectomy. However, it will be of interest to review the general biology of the endocrine system in the broadest terms.

II

The enormous energy developed in the zygote provides the impetus which carries the organism on its passage through life. It is perhaps somewhat fanciful but it does remind one of the release of atomic energy. At that moment growth is at its maximum and measured in fractions from that original impetus there is a steady decline in the rate of growth. It has even been asserted that at the moment of birth not more than 2% of that original impetus remains. The organism may be compared to a projectile whose initial velocity constantly diminishes from the moment of its discharge. It does not escape from the second law of thermodynamics, though, as Hopkins shrewdly pointed out, it is the function of life to hold up that dissipating energy at a useful level.

For the last twenty years and more interest has concentrated, however, on the quality rather than on the quantity of growth. The experimental embryological studies, particularly of Roux and of Spemann, revealed amazing facts about the "organizer". At an early stage the graft of embryonic tissue from the dorsal lip of the blastopore is capable of imposing its inherent potentialities on its new environment. As we know, in this way a neural canal is formed on any part of the embryo receiving the implant. Yet at a slightly later stage the implant has to accept the structural development of its host. Clearly specialization of organizing material has already begun. A new interest was aroused by Joseph Needham's demonstration that this "organizer" did not depend on cellular structure; the potent material could be crushed, frozen, or even boiled. Indeed, boiling seemed to set it free and increased the scope of its activities. Therefore it obviously was not a ferment. He found that chemically it was a sterol, reminding us at once of the chemical structure of certain hormones. All this work proves that chemical controls are actively at work before any trace of a nervous system has appeared.

Indeed, it is freely recognized that organisms are controlled by several mechanisms before any semblance of a nervous system has appeared in evolution. Chemotropism may be the most powerful but by no means the only control of this order. It lies too far outside my present topic to give illustrations of stereotropism, heliotropism and so forth; though the subject opens a fascinating vista. We are concerned at this stage with the chemical controls and may regard hormones as a specialized and concentrated form of this. In other words, hormones appeared before the glands which were to house them. Comparative morphology presents a good deal of evidence that many of the recognized endocrine glands had a more primitive function than that which they now possess. Thus in the worms and Peripatus there are paired nephridia in every segment. By their means the function to which Claude Bernard attached such fundamental importance, the constancy of the internal medium, is secured. In higher forms of life changes in structure and habitat rendered this method unsuitable. The posterior nephridia were condensed to form the functioning metanephros while some of the more anterior ones became modified to house some of the endocrines. In fact the whole process reminds us of the hermit crab which existed before it found an empty whelk shell for an abode. Thus J. F. Gaskell, continuing his father's researches, showed that in the lamprey there was a wide distribution of adrenalin-secreting cells, though as development increased these became almost entirely confined to the medulla of the adrenal.

Considering the struggle the central nervous system displayed to obtain control of the body it is not likely that it would abdicate in favour of mere chemical controls. The anatomical arrangements of the sympathetic nervous system admirably adapts it to the rapid production of widespread effects. Failure to recognize this was the error into which earlier endocrinologists fell; although the close anatomical association between the nervous and glandular elements of for example the pituitary and adrenal should have prevented this. This close association having once been achieved it was never dropped, showing that it must be of great advantage to the organism. Pathology illustrates this by the observation that in anencephalic monsters the fusion between cortical and medullary portions of the adrenal does not occur.

The intimate nature of the association between chemical and nervous factors was triumphantly demonstrated by the work of Loewi and of Dale. They showed by the

recognition of cholinergic and adrenergic nerve endings that every nervous stimulus was mediated through a chemical mechanism before affecting the tissue cell. This generalization has greatly clarified our whole outlook.

Although the essential cause of cancer is still unknown it would be generally agreed that it is characterized by a complete breakaway of the growth factors from nervous control. It is, therefore, not surprising that the chemical similarity between hormones as regulators of normal metabolism and carcinogens as stimulators of abnormal growth has excited much interest and perhaps not unnaturally some apprehension. This association between all growth-promoting and differentiation-promoting agents comes out in a very striking way if amphibian eggs are subjected to what is known as "delayed fertilization". To quote Joseph Needham's account of the work "the longer the eggs wait for the sperm cells the more virulent is the subsequent dislocation of development. If the delay is short, serious unbalance of the sex-ratio ensues (due to interference with the formation of the sex hormones?); if the delay is longer, multiple liberation or formation of the organizer takes place, and multiple monsters result; if the delay is very long, development runs an extremely abnormal course, giving shapeless teratomata and these if implanted into an adult frog will give malignant growth, including even metastases. This gradual transition from the normal to the frankly malignant must surely depend on purely environmental factors. It is, indeed, in connexion with the sex hormones that the overlap between the stimulus for cancer production and the stimuli for the sexual cycle is most obvious. But this overlap is also seen between the oestrogens and the primary organizer. Thus Waddington and D. M. Needham were able to produce secondary neural axes in host embryos by the implantation of certain synthetic oestrogenic hydrocarbons. There is strong support for the opinion that the primary organizer is a sterol-like substance. In view of the exceedingly wide distribution of the primary organizer and the presence of oestrogens in coal-tar, it is significant that oestrogens have been found to exist in some plant tissues. This at once reminds us of those other exogenous hormones, the vitamins, but I am deliberately excluding them from this survey, other than to refer to the sterol-like character of vitamin D; thus providing us with another example of overlap between the various growth factors.

The part played by hormones both in physical and psychological manifestations is so closely interwoven in the whole organism that while taking a special interest in them we incorporate them in the general body of medicine. This would accord with the present tendency to adopt a psychosomatic attitude in medicine.

Addison's Disease and Pregnancy.—S. LEONARD SIMPSON, M.D.

This is a case of Addison's disease in a woman of 30, characterized by the onset of symptoms during pregnancy some four years ago, and the occurrence of a second successful pregnancy, terminating in a second live child recently, but with failure of lactation after both parturitions. I have seen two other patients with Addison's disease survive pregnancy and a few have been published, but this patient appears to be the first recorded example of Addison's disease and two pregnancies, as well as two live children. Pigmentation occurs physiologically during pregnancy in normal women, probably due to temporary inadequacy of adrenal function, the physiological hypertrophy of the adrenal cortex indicating that the increased function is called for by pregnancy, the undestroyed portion of the adrenal gland in Addison's disease being sufficient in the earlier phase of the disease for normal purposes but not for the added requirements of pregnancy.

The patient married some five years ago, and became pregnant after six months. Some pigmentation of the face and hands was noticed during the fifth month of this first pregnancy, and from that time the patient complained of tiredness and malaise. However, the pregnancy and parturition were normal but lactation failed. The first child was born in December 1943. Although lactation failed, amenorrhœa persisted until August 1944, when normal monthly menstruation occurred and continued, but an occasional period was missed. Her health was indifferent, and general malaise was noticed. The pigmentation, which had faded somewhat after parturition, gradually returned, and she lost two stone in weight. In August 1944, the patient was admitted to Queen Elizabeth Hospital, Birmingham, in semi-coma, and with a blood-pressure of 80/60. The diagnosis of Addison's disease was made, and she responded to intravenous saline and later maintained imperfect health on 4 grammes of salt a day without cortical extract.

The patient was first seen by me in November 1944, complaining of weakness and malaise. She had pigmentation of the skin, as in Addison's disease, but not of the mucous membranes. She was still taking salt. Her blood-pressure was 90/60; serum potassium 20.1 mg., serum sodium 305 mg. and serum chloride 586 mg., and the Kepler test was positive for Addison's disease, under 12.4. She responded clinically to 10 c.c. eucortone daily, and after some weeks, to 5 mg. of desoxycortone daily instead of the eucortone; and the sodium chloride was increased to 8 grammes a day. Her blood chemistry became normal on this dosage. In February 1945, I implanted in the subcutaneous tissue of the abdomen 6 by 100 mg. of desoxycortone, and continued the salt intake of 8 grammes a day. The patient remained very well. B.P. 120/80. In May 1945, she complained of two months' amenorrhœa. This was at first thought to be part of

recognition of cholinergic and adrenergic nerve endings that every nervous stimulus was mediated through a chemical mechanism before affecting the tissue cell. This generalization has greatly clarified our whole outlook.

Although the essential cause of cancer is still unknown it would be generally agreed that it is characterized by a complete breakaway of the growth factors from nervous control. It is, therefore, not surprising that the chemical similarity between hormones as regulators of normal metabolism and carcinogens as stimulators of abnormal growth has excited much interest and perhaps not unnaturally some apprehension. This association between all growth-promoting and differentiation-promoting agents comes out in a very striking way if amphibian eggs are subjected to what is known as "delayed fertilization". To quote Joseph Needham's account of the work "the longer the eggs wait for the sperm cells the more virulent is the subsequent dislocation of development. If the delay is short, serious unbalance of the sex-ratio ensues (due to interference with the formation of the sex hormones?); if the delay is longer, multiple liberation or formation of the organizer takes place, and multiple monsters result; if the delay is very long, development runs an extremely abnormal course, giving shapeless teratomata and these if implanted into an adult frog will give malignant growth, including even metastases. This gradual transition from the normal to the frankly malignant must surely depend on purely environmental factors. It is, indeed, in connexion with the sex hormones that the overlap between the stimulus for cancer production and the stimuli for the sexual cycle is most obvious. But this overlap is also seen between the oestrogens and the primary organizer. Thus Waddington and D. M. Needham were able to produce secondary neural axes in host embryos by the implantation of certain synthetic oestrogenic hydrocarbons. There is strong support for the opinion that the primary organizer is a sterol-like substance. In view of the exceedingly wide distribution of the primary organizer and the presence of oestrogens in coal-tar, it is significant that oestrogens have been found to exist in some plant tissues. This at once reminds us of those other exogenous hormones, the vitamins, but I am deliberately excluding them from this survey, other than to refer to the sterol-like character of vitamin D; thus providing us with another example of overlap between the various growth factors.

The part played by hormones both in physical and psychological manifestations is so closely interwoven in the whole organism that while taking a special interest in them we incorporate them in the general body of medicine. This would accord with the present tendency to adopt a psychosomatic attitude in medicine.

was almost identical with that of his brother. The right testis was infantile but in the scrotum. The left was ectopic and palpable just over the pubis. His height was 67 inches. (fig. 2.) He responded in similar fashion to a testosterone implant.

FIG. 1.
Thomas, aged 18.

FIG. 2.
Daniel, aged 22.

Differential diagnosis.—Infantilism involves (1) infantile sexual development; (2) sub-normal growth in height and breadth; (3) delay in epiphyseal union, and (4) a graceful delicate appearance (Levi-Lorain type). The primary defect in infantilism is pituitary, the gonadal defect being secondary.

In eunuchoidism there is a primary failure of gonadal development. The height is usually above normal, but may be normal, and the span is greater than the height. It is rarely recorded as below average normal, although I have such definite cases. Eunuchoids are usually described as being adipose, but it is not generally recognized that both eunuchoids and pre-pubertal castrates may be quite thin. (I have one example of the latter.) Growth continues until the late twenties, or later, as the epiphyses are ununited and the pituitary growth hormone continues to be secreted. Both patients had mumps at the age of 5, but as far as is known, this was not complicated by obvious orchitis.

In view of the continued growth in height and the failure of response to gonadotrophic hormone, as well as the eunuchoid proportion of span and height, I favour the diagnosis of eunuchoidism in these brothers. (The estimation of gonadotrophins in blood and urine was not carried out.) It is probable that their ultimate height may be well above normal. However, both of them, at the age of 14 or even 16, were well below the average height of their friends. They were below 5 ft. in height. It is not generally recognized that this may be the case in eunuchoids, and was true in one of my eunuchoid patients who is now 6 ft. 3 in. The cause of this is probably the absence of testosterone secretion, which providing that it does not produce closure of the epiphyses, has an important stimulating effect on growth. It would therefore appear that at the age of 14, or even 16, these two brothers gave a clinical picture of infantilism, although to-day the correct diagnosis appears to be eunuchoidism.

Gynæcomastia with Bilateral Undescended Testes in a Man aged 21.—J. S. RICHARDSON, M.D. (St. Thomas's Hospital).

Raymond D., aged 21, first noticed swelling of his breasts at the age of 16, at which time they were tender and painful. They have remained enlarged but have been less tender during the last year. He experiences more pain when the weather is cold. The

the adrenal disorder, as she had missed menstruation occasionally. In August 1945, on abdominal examination, a swelling was felt in the suprapubic area, and pregnancy was discovered. She remained very well, although the blood-pressure was 98/60, and serum sodium 307 mg. The serum chloride was 618 mg. and potassium 17 mg. There had been no disturbance of any kind during the initial period of pregnancy. She continued very well throughout the pregnancy on 5 mg. desoxycortone injected daily, and 12 grammes of salt daily, the blood-pressure averaging 100/75.

As Willesden General Hospital has no obstetric department, she was transferred for the parturition to Central Middlesex Hospital under Dr. Avery Jones and Mr. J. S. McVine. Treatment was continued with desoxycortone, with salt, as previously, and without any change. On November 30, 1945, she was delivered of a male baby, weight 6 lb. 10 oz., after a normal labour of sixteen hours. The baby was normal except for a mild degree of hypospadias. Her systolic blood-pressure remained between 100 and 120 mm.Hg, and there were no unusual symptoms. Lactation, however, failed, and artificial feeding difficulties were met with but overcome.

The patient was seen by me on January 4, 1946, and was very well. On January 18 she complained of swelling of the face. Blood-pressure was 160/105. This indicated excessive treatment. The desoxycortone was continued, but salt therapy stopped. On February 1 she was very well, B.P. 140/100. A clinical assistant saw her and again ordered 8 grammes of salt a day. The œdema of the face returned; and salt was then again stopped.

The patient is now in good condition. B.P. 125/80.

Comment.—Pregnant animals survive adrenalectomy for longer periods than normal animals. This may be due to hypertrophy of the anterior pituitary gland with (a) increased secretion of diabetogenic hormone, (b) increased secretion of adrenocorticotrophic hormone which stimulates accessory adrenal cortex tissue and (c) increased secretion of progesterone. In women, the uninjured part of the adrenal cortex probably undergoes hypertrophy and there is also a possibility of the adrenal cortex of the fœtus helping to compensate for the mother's deficiency. It is known that the adrenal cortex plays an important part in lactation, which fails in adrenalectomized animals maintained on inadequate doses of cortical extract. The patient might have lactated if the desoxycortone had been replaced by cortical extract containing the carbohydrate corticosterone factor.

Two Brothers, with Infantilism or Eunuchoidism.—S. LEONARD SIMPSON, M.D.

These patients are presented because of the rarity of the condition, and the differential diagnosis.

Thomas, aged 18, was first seen by me at Willesden General Hospital Endocrine Clinic in September 1945, being referred for "undeveloped testes". He had a boyish appearance, and shy, diffident manner. His weight was 7 stone, height 67 inches, and span 71 inches. His shoulders were slightly broader than his pelvis, but his general appearance was graceful and fragile. His fingers and toes were long and slender. There was an absence of fat generally. The penis was tiny and the testes not palpable. No hair was present on the face, pubis or axillæ, and the voice was high-pitched and unbroken (fig. 1). B.P. 125/80. Pulse 80. Fundi normal. X-ray (Dr. Rohan Williams): "Pituitary fossa smaller than average; delayed epiphyseal closure—average for male of 15". 17-ketosteroids in urine (Dr. W. Payne): 4.6 mg. per day; 3.2 mg. per litre.

Treatment.—In October 1945, I implanted under local anaesthesia 8 tablets of 100 mg. each of testosterone propionate in the subcutaneous tissue of the abdomen.

Result.—Frequent penile erections started after one week. Appetite, weight (1 stone in four weeks) and strength were greatly increased. He had increased 1 inch in height, and his shoulders were broader. The voice was deeper. The penis was enlarged, and there was an interesting area of redness (erythema) over the pubis, pelvis, and scrotum. Some hair was growing on the pubis. To-day his weight is 9 stone 3 lb. and his height 69 inches. Hair is plentiful on the pubis (but limited horizontally) and in the axillæ but little on the face. His manner is much more forthcoming and enterprising. The penis is larger; the right testis is infantile and now felt in the scrotum; the left is not palpable.

The brother, Daniel, aged 22, came to hospital because of the great improvement in Thomas, and because he had failed to respond in any way to a course of chorionic gonadotrophins (500 units injected twice weekly for six weeks). His general appearance

was almost identical with that of his brother. The right testis was infantile but in the scrotum. The left was ectopic and palpable just over the pubis. His height was 67 inches. (fig. 2.) He responded in similar fashion to a testosterone implant.

FIG. 1.
Thomas, aged 18.

FIG. 2.
Daniel, aged 22.

Differential diagnosis.—Infantilism involves (1) infantile sexual development; (2) sub-normal growth in height and breadth; (3) delay in epiphyseal union, and (4) a graceful delicate appearance (Levi-Lorain type). The primary defect in infantilism is pituitary, the gonadal defect being secondary.

In eunuchoidism there is a primary failure of gonadal development. The height is usually above normal, but may be normal, and the span is greater than the height. It is rarely recorded as below average normal, although I have such definite cases. Eunuchoids are usually described as being adipose, but it is not generally recognized that both eunuchoids and pre-pubertal castrates may be quite thin. (I have one example of the latter.) Growth continues until the late twenties, or later, as the epiphyses are ununited and the pituitary growth hormone continues to be secreted. Both patients had mumps at the age of 5, but as far as is known, this was not complicated by obvious orchitis.

In view of the continued growth in height and the failure of response to gonadotrophic hormone, as well as the eunuchoid proportion of span and height, I favour the diagnosis of eunuchoidism in these brothers. (The estimation of gonadotrophins in blood and urine was not carried out.) It is probable that their ultimate height may be well above normal. However, both of them, at the age of 14 or even 16, were well below the average height of their friends. They were below 5 ft. in height. It is not generally recognized that this may be the case in eunuchoids, and was true in one of my eunuchoid patients who is now 6 ft. 3 in. The cause of this is probably the absence of testosterone secretion, which providing that it does not produce closure of the epiphyses, has an important stimulating effect on growth. It would therefore appear that at the age of 14, or even 16, these two brothers gave a clinical picture of infantilism, although to-day the correct diagnosis appears to be eunuchoidism.

Gynæcomastia with Bilateral Undescended Testes in a Man aged 21.—J. S. RICHARDSON, M.D. (St. Thomas's Hospital).

Raymond D., aged 21, first noticed swelling of his breasts at the age of 16, at which time they were tender and painful. They have remained enlarged but have been less tender during the last year. He experiences more pain when the weather is cold. The

breasts have never secreted. His voice has not broken but pubic hair appeared at the age of 14 and his penis began to enlarge at that time continuing to do so until he was 20. His sexual interests are homosexual and he suffers from prolonged and frequent erections but has never had ejaculations.

Previous health.—Mumps, measles, chickenpox before the age of 10. An operation for bilateral hernia at the age of 7; no information as to whether left testis was removed is available.

Family history.—No evidence of endocrine disorder. Patient is youngest of five by fifteen years.

On examination.—He is a poor physical specimen without a beard and with scanty body hair. Height 68½ in.; span 68½ in.; sole to pubis 34 in. He has bilateral gynæcomastia with easily felt glandular tissue and the aureolæ are pigmented without being enlarged. His penis is large; his left testis impalpable; the right at the external inguinal ring is small; the prostate is very small. Urinary hormone assays—17-ketosteroids, 16.4 mg. in twenty-four hours; alpha fraction 80-90%; follicular stimulating hormone (F.S.H.) 320 M.U. in twenty-four hours; no luteinising effect; œstrogens in urine—10 gamma in twenty-four hours.

It is thought that this case is an example of the syndrome described by Klinefelter *et al.* (1942) and expanded by Nelson and Heller (1945). Our case had bilateral gynæcomastia occurring in an adolescent with presumptive evidence of tubular degeneration, as there was bilateral cryptorchidism. The Leydig cell function was adequate as evidenced by a large phallus and normal quantitative and qualitative 17-ketosteroid excretion and there was excess follicular stimulating hormone (F.S.H.) in the urine. It is known that eunuchoids and castrates who have excess F.S.H. and only extratesticular androgen do not get gynæcomastia but that these, if adolescent, may develop gynæcomastia when treated with testosterone.

It is tentatively suggested that the development of gynæcomastia in the group of cases to which we believe this one belongs, depends on an excess of F.S.H. and the presence of an adequate supply of androgen.

Chronic Idiopathic Hypoparathyroidism.—J. S. RICHARDSON, M.D. for H. GARDINER-HILL, M.D., F.R.C.P.

N. C., aged 16, was first admitted to St. Thomas's Hospital under the care of Dr. Gardiner-Hill on April 25, 1941. He was 7 lb. at birth and walked late—at 2 years. He first had epileptiform fits at 18 months and these continued intermittently until he was given epanutin at the age of 10. Various diagnoses were made such as epilepsy, poliomyelitis and spastic diplegia, the last two because of the deformity of his legs and feet. These were first noticed when he began to have severe cramps in his legs and later arms, at the age of 5. His feet turned in and he had difficulty in walking, with almost constant spasm that had been worse for two years.

On examination he had a strongly positive Chvostek's sign and carpopedal spasm with bilateral pes cavus. The blood calcium was 4.1 mg.%; inorganic phosphate 9.9 mg.%; blood urea 37 mg.%. Urine normal. Bilateral cataract. No significant changes in his bones.

Treatment.—Parathormone 60 units daily for fourteen days did not control his cramps and he had several epileptiform convulsions. Blood calcium 5.4 mg., phosphate 8.8 mg. Treatment was changed to ostelin 120,000 units and calcium gluconate one ounce daily. After three weeks, the calcium was 8.2 mg., phosphate 7 mg. and after five weeks calcium 8.2 mg. and phosphate 4 mg. These figures remained more or less constant for several months. He was discharged on January 1, 1942 on 150,000 units of ostelin and one and a half ounces of calcium gluconate daily, the blood calcium then being 10.2 mg., phosphate 6 mg. All other investigations proved negative except the blood urea that remained round about 40 mg.

After an operation for bilateral pes cavus in June 1943 his blood calcium was 18 mg.%. No evidence of metastatic renal calcification was found. From that time he has been on halibut liver oil capsules 1,000 units and calcium gluconate half an ounce daily, with a calcium level of about 9.0-11.0 mg. and inorganic phosphate of 4 mg. On February 20, 1946, his serum calcium was 8.0 mg., inorganic phosphate 4.4 mg.

These cases of chronic idiopathic hypoparathyroidism are rare. Rose in 1943, could only find some 70 odd in literature. The association of epilepsy is well recognized but only recently have E.E.G. changes, suggestive of epilepsy, been demonstrated in hypoparathyroidism, and these made to disappear by adequate medical treatment or surgical implants (Odoriz, 1944, Taubenhau and Engle, 1945). This case did not respond to parathormone but was well controlled by large doses of vitamin D, and in this is similar to three cases described by Albright *et al.* (1942).

Hypogonadism (Eunuchoidism) with Ununited Epiphyses.—HUGH DUNLOP, F.R.C.P. and PHILIP ELLMAN, F.R.C.P.

G. T. F., aged 36, cook, was referred to the Out-patients Department of one of us (P. E.) at the Rheumatism Unit at St. Stephen's Hospital as a case of "rheumatism."

He complained of pain in the left shoulder and forearm on and off since 1938. He has had similar pain in right shoulder and lumbar region.

Previous history.—1924, influenza.

On examination.—Pallid individual, "myxoedematoid" facies, looking younger than his age with a rather effeminate voice; hair on face and axillæ very scanty, no hair on the chest and pubic hair is of feminine type with a concave upward margin. He shaves only once every three weeks. External genitalia normal; testes descended and normal.

Heart, lungs, abdomen, central nervous system, were normal. Blood-pressure normal. Pulse 58.

Examination of the locomotor system shows large hands and feet with long slender fingers (figs. 1 and 2).

No pain, tenderness or swelling of the joints. He has limitation of extension of the elbows due to a chondroostrophy.

FIG. 1.

FIG. 2.

Note the myxoedematoid facies, absence of hair on the chest, large hands and long slender fingers.

X-rays of his hands, knees, and feet show delayed union of the epiphyses with an epiphyseal age of about 18.

X-ray of skull shows a deep pituitary fossa, which is normal in size.

All urinary investigations were normal. Volume of urine 1,360 c.c. per day. 17-ketosteroids 3.3 mg. per litre or 4.5 mg. per day.

Blood-count normal. Blood cholesterol 141 mg. %.

He was referred by one of us (H. D.) to Mr. Broster's Endocrine Clinic where he was considered a suitable case for testosterone implant of 600 mg. which up to date he has refused.

The delay in union of the epiphyses is consistent with the diagnosis of hypogonadism.

Whether this is a so-called "primary" hypogonadism, or due to a defect elsewhere in the endocrine system, is debatable.

Cushing's Pituitary Basophilism treated successfully by Deep X-ray Therapy.—PHILIP ELLMAN, F.R.C.P., and G. VILVANDRÉ, M.R.C.S., L.R.C.P.

Case shown to the Clinical Section by one of us (P. E.), November 1934 (*Proc. R. Soc. Med.* 28, 335). She had several courses of X-ray therapy until 1939 and we have convincing evidence of its beneficial effects in this case.

Her general appearance is now normal; she has lost her hirsutism and her florid complexion. She is now no longer obese; she has lost an appreciable amount of weight—weight loss from 9 st. 3 lb. to 8 st. Her blood-pressure is normal, 120/70. There are no abnormal findings in the cardiovascular system. Central nervous system normal.

She has no pigmentation of the legs or discoloration of the skin.

All urinary investigations are negative.

Her blood-count is normal; there is now no œdema.

X-ray treatment has proved beneficial in so far as: (1) There has been a resumption of menses with normal loss. (2) Blood-pressure is normal. (3) There is now no polycythæmia. (4) Her appearance is normal and her weight is now normal. (5) Her condition has shown progressive improvement to practically a normal state since it was first detected in 1934. (6) She has no headaches.

Mr. Northfield has seen her and has regarded the results as so satisfactory that any question of surgery does not arise.

Dr. A. C. CROOKE: It is difficult to assess the effect of any treatment in Cushing's disease because of the natural fluctuation in severity of the symptoms from time to time and because occasionally symptoms disappear completely without any treatment. Cushing originally claimed that radiotherapy was the treatment of choice but I have sections of the pituitary glands of his patients which he once claimed to have cured! Our own experience of radiotherapy has been equally disappointing and I have had the opportunity of examining sections of pituitary glands from patients who have died in spite of intensive X-ray treatment and found no histological changes in them. This is in marked contrast to the large areas of necrosis caused by the implantation of radon seeds into the pituitary gland which results in a dramatic cure of basophilism in a short time. The purple striæ atrophicæ change to pink within twenty-four hours, the patient loses weight and the other symptoms subside more gradually. This method of treatment was first described by the late Mr. Pattison in 1938 and seems to me to be the most promising one at present available but it is liable to cause signs of pituitary insufficiency if too large a dose is given.

Male Gynæcomastia: Testicular Atrophy.—A. C. CROOKE, M.D.

K. E., a married soldier, aged 24, complains of painful swelling of the right breast of eight months duration. Subsequently the left breast became similarly swollen and painful. An operation was performed at the age of 14 to bring the right testicle down into the scrotum but it subsequently retracted. The left is in the normal position but has always been rather small. He has normal intercourse but no ejaculations. Pubic and axillary hair appeared at puberty but he only shaves twice a week and his voice has never broken.

On examination.—Masculine habitus except for a diffuse tender enlargement of the right breast and less of the left. Large areolæ and nipples. Scanty moustache and beard and female distribution of pubic hair. Penis and scrotum normal but testes small.

17-ketosteroid output 23 to 25.9 mg. in twenty-four hours.

Testicular biopsy: Marked atrophy of seminiferous tubules and great hyperplasia of interstitial cells.

Breast biopsy: Much fat. Rather sparse fibrous tissue and a few scattered ducts.

Treatment of Ulcerative Colitis with Intestinal Mucosa

By A. MORTON GILL, M.D.

Study of the natural course of ulcerative colitis, with its tendency to spontaneous remissions and relapses, led me to consider whether, in some cases at least, the condition might not be the result of a deficiency. Preliminary investigations suggested that this deficiency might result from lack of some factor and that this hypothetical factor might be produced in or by some portion of the small intestine. This idea could best be tested by feeding raw small intestine to a victim of ulcerative colitis who had failed to respond to orthodox therapy and who had gone for a long time without remission of his disease.

About nine years ago there came under my care a man who had had the disease for three years, including one year in hospital, without showing improvement. Treatment with raw pig's small intestine by mouth resulted in a remission which was maintained so long as he took the treatment. When supplies failed (fig. 1) he relapsed. When supplies were again obtainable he became well. Figs. 2 and 3 show what happened when he voluntarily ceased treatment and when he started it again, namely, first a relapse and then a remission. At this time dried preparations of pig's small intestinal mucosa became available. There were two preparations, A (Benger's) in which enzymal activity was retained and B (Allen and Hanbury's). On A there was little or no improvement, on B a complete remission within a month (fig. 4). Table I summarizes this case.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 1.—April 4, 1941: Relapse as runners became unobtainable. At A, feeling well, no pain, normal stools; weight 11 st. 12 lb. At B, pain, diarrhoea, blood and mucus in stools, lassitude; weight 11 st. 4 lb.

FIG. 2.—Nov. 7, 1942: Relapse when runners were discarded voluntarily. At A, feeling well and at work; no pain, normal stools. At B, too ill to work, easily tired; pain, diarrhoea, faecal incontinence, blood and mucus in stools.

FIG. 3.—Jan. 30, 1943: Slow improvement when taking runners. At A, off work; pain, lassitude, blood in stools. At B, feeling well and working overtime; no pain, normal formed stools.

FIG. 4.—Course of Case I. From May, 1944 to January, 1945, each dot represents two days; thereafter each dot represents one day.

Acknowledgments: Figs. 1, 2 and 3 appeared in *Lancet*, 1944 (i), 536, and fig. 4 in *Lancet*, 1945 (ii), 203.

During the war I saw few cases of ulcerative colitis. Table II tabulates these, showing a response to raw pig's small intestine in 3 cases, no improvement in 2.

Of 3 further cases treated with preparation A, none showed material improvement. Of 12 further cases treated with preparation B, 8 became completely well and have

X-ray of skull shows a deep pituitary fossa, which is normal in size.

CROOKE: It is difficult to assess the effect of any treatment in Cushing's disease because of the natural fluctuation in severity of the symptoms from time to time and because occasionally symptoms disappear completely without any treatment. Cushing originally claimed that radiotherapy was the treatment of choice but I have sections of the pituitary glands of his patients which he once claimed to have cured! Our own experience of radiotherapy has been equally disappointing and I have had the opportunity of examining sections of pituitary glands from patients who have died in spite of intensive X-ray treatment and found no histological changes in them. This is in marked contrast to the large areas of necrosis caused by the implantation of radon seeds into the pituitary gland which results in a dramatic cure of basophilism in a short time. The purple striæ atrophice change to pink within twenty-four hours, the patient loses weight and the other symptoms subside more gradually. This method of treatment was first described by the late Mr. Pattison in 1938 and seems to me to be the most promising one at present available but it is liable to cause signs of pituitary insufficiency if too large a dose is given.

PATTISON, A. R. D., and SWAN, W. G. A (1938) *Lancet* (i), 1265.

Male Gynæcomastia; Testicular Atrophy.—A. C. CROOKE, M.D.

K. E., a married soldier, aged 24, complains of painful swelling of the right breast of eight months duration. Subsequently the left breast became similarly swollen and painful. An operation was performed at the age of 14 to bring the right testicle down into the scrotum but it subsequently retracted. The left is in the normal position but has always been rather small. He has normal intercourse but no ejaculations. Pubic and axillary hair appeared at puberty but he only shaves twice a week and his voice has never broken.

On examination.—Masculine habitus except for a diffuse tender enlargement of the right breast and less of the left. Large areolæ and nipples. Scanty moustache and beard and female distribution of pubic hair. Penis and scrotum normal but testes small.

17-ketosteroid output 23 to 25.9 mg. in twenty-four hours.

Testicular biopsy: Marked atrophy of seminiferous tubules and great hyperplasia of interstitial cells.

Breast biopsy: Much fat. Rather sparse fibrous tissue and a few scattered ducts.

such a serious problem. He had always been impressed by the similarity of acute ulcerative colitis to mercurial poisoning as if the process consisted of eliminating some toxic product from the mucosa.

Dr. F. Avery Jones suggested that new treatments for colitis would have good results if given with enthusiasm. The patient with this chronic illness was particularly susceptible to emotional factors. This made the assessment of new remedies particularly difficult and it was important to have a control series using some similar but presumably inert preparation.

Dr. W. A. Oliver said that he had had a recent experience of a case of ulcerative colitis with a bad relapse lasting seven months, who failed to show any improvement with rest in bed and conservative treatment, but who responded dramatically following enthusiastic treatment with "Pepsac" (hog's stomach). Perhaps this would be an example of the control treatment with an inert powder suggested by Dr. Avery Jones.

Some Observations on the *Ætiology* and Treatment of Sprue

By A. L. WINGFIELD, M.D.

THE main features of tropical sprue are flatulent dyspepsia with abdominal distension and frequent bulky, pale, frothy and fatty stools. Cheilosis, glossitis, anæmia, and gross emaciation may be regarded as important but secondary manifestations. Clinically the primary dysfunction is a failure of intestinal absorption, while the secondary features result from deficiency of vitamins, foodstuff, or hæmatinic principle.

Of the morbid anatomy very little is known. The classical descriptions of atrophy and dehydration of all the main viscera and of the intestines are entirely correct but apply only to extreme cases with fatal issue. Practically nothing is known of the gross anatomical or of the histological changes in the earlier stages, but the very rapid response to correct treatment leads to the supposition that no serious change of structure occurs until the disease is far advanced, and Stannus has said that there are no early pathological changes. It is unlikely that much progress will be made in this direction as there is no real occasion, or should one say excuse, for biopsy observation, and death from intercurrent conditions is uncommon. It is not possible to produce the syndrome in experimental animals.

In the matter of *ætiology* some progress is being made. Infection is thought to play a definite part and the evidence for this cited by Galloway (1905) was reinforced by Manson-Bahr (1915) and more recently by Leishman (1945), but convincing proof is still lacking. The importance of vitamin deficiency is evidenced by the cheilosis, glossitis, and by the response to treatment. Stannus (1942) showed that failure of phosphorylation might account for the faulty absorption of fat and of glucose, while Leishman (1945) has elaborated this interesting theory by suggesting that nicotinic acid and riboflavin, which occur in the body in phosphorylated form, are able to catalyse phosphorylation and that the process of intestinal bio-synthesis of vitamins is subject to gross interference by an infective agent. The relationship of sprue to pellagra is entirely fortuitous and there is no common *ætiological* factor. Chronic jejuno-ileal insufficiency as suggested by Bennett and Hardwick (1940) has a superficial attraction but does not help in elucidating the *ætiology*. Hurst (1942) put forward a theory that paralysis of the muscularis mucosæ leads to a loss of the pumping action of the villæ, but there is no acceptable evidence to support this suggestion. Radiological abnormalities have been much discussed but they require highly specialized interpretation and do not help either in elucidating the cause or in giving guidance as to correct treatment. The occurrence of macrocytic anæmia, even in the presence of gastric hydrochloric acid, suggests a failure of absorption of hæmatinic principle from the intestinal tract rather than a failure of production by the gastric mucosa. If it can be accepted that anæmia is a result only of failure of intestinal absorption of hæmatinic principle, Manson-Bahr's (1941) and de Langen and Lichenstein's (1936) recognition of the many parallel features of sprue and pernicious anæmia lose some of their significance, and the similarity of the two conditions becomes logical. Present evidence seems to point to a failure of the intestinal mucosa to perform its normal function of absorption and, if this one assumption proves to be correct, all the clinical manifestations of the syndrome are to be regarded as the direct result of this one derangement. The very rapid response to treatment points strongly to a disorder of function rather than of structure, but, for the time being, most of our ideas about the *ætiology* of this syndrome are based upon clinical observation unsupported by controlled experiment.

Stannus says: "There is a functional derangement of the bowel due to deficient fat absorption and not deficient fat absorption due to paralysis of the muscularis mucosæ of its wall."

This aspect requires further detailed investigation which should include comparative analysis of food intake and fæcal output, and experiment to demonstrate, if possible, the

remained so, relapsing on ceasing treatment, regaining health on re-starting the extract (Table III).

In conclusion I would make the following points:

(1) That the term ulcerative colitis covers more than one disease, or, alternatively, that the aetiology of all cases of ulcerative colitis is not the same.

(2) That in one group of cases the cause may lie in some deficiency caused by a lack of some factor produced by the small intestine. Treatment of some cases of ulcerative colitis with intestinal mucosa has given promising results.

(3) Increasing the dose of desiccated mucosa beyond 1 oz. (= ½ lb. raw material) daily produces no better results. On the other hand, a small dose (e.g. 1 drachm daily)

TABLE I—SUMMARY OF CASE 1.

3 years' continuous symptoms. 1 year routine treatment—no improvement

					27	F	4 years	Preparation B for 6 weeks	Well

is without effect. In all cases there is a latent interval of about three weeks before any appreciable improvement is noted.

(4) Mucosa taken from the different anatomical segments of the small intestine seems to be effective, although possibly jejunal mucosa produces a more lasting effect.

(5) A new highly concentrated preparation (Allen and Hanbury) is now on trial. 1 drachm = 1 oz. of preparation B. It has so far been given to a small number of patients.

(6) The mode of action of this form of therapy is still unproven.

Sir Philip Manson-Bahr said that the proposition of Dr. Morton Gill was an attractive one, and it had always seemed to him that ulcerative colitis was due rather to some inbred cause than to an extraneous infection. But he was doubtful whether this method of treatment had any effect upon those extremely toxic fulminating cases that presented

such a serious problem. He had always been impressed by the similarity of acute ulcerative colitis to mercurial poisoning as if the process consisted of eliminating some toxic product from the mucosa.

Dr. F. Avery Jones suggested that new treatments for colitis would have good results if given with enthusiasm. The patient with this chronic illness was particularly susceptible to emotional factors. This made the assessment of new remedies particularly difficult and it was important to have a control series using some similar but presumably inert preparation.

Dr. W. A. Oliver said that he had had a recent experience of a case of ulcerative colitis with a bad relapse lasting seven months, who failed to show any improvement with rest in bed and conservative treatment, but who responded dramatically following enthusiastic treatment with "Pepsac" (hog's stomach). Perhaps this would be an example of the control treatment with an inert powder suggested by Dr. Avery Jones.

Some Observations on the *Ætiology* and Treatment of Sprue

By A. L. WINGFIELD, M.D.

THE main features of tropical sprue are flatulent dyspepsia with abdominal distension and frequent bulky, pale, frothy and fatty stools. Cheilosis, glossitis, anæmia, and gross emaciation may be regarded as important but secondary manifestations. Clinically the primary dysfunction is a failure of intestinal absorption, while the secondary features result from deficiency of vitamins, foodstuff, or hæmatinic principle.

Of the morbid anatomy very little is known. The classical descriptions of atrophy and dehydration of all the main viscera and of the intestines are entirely correct but apply only to extreme cases with fatal issue. Practically nothing is known of the gross anatomical or of the histological changes in the earlier stages, but the very rapid response to correct treatment leads to the supposition that no serious change of structure occurs until the disease is far advanced, and Stannus has said that there are no early pathological changes. It is unlikely that much progress will be made in this direction as there is no real occasion, or should one say excuse, for biopsy observation, and death from intercurrent conditions is uncommon. It is not possible to produce the syndrome in experimental animals.

In the matter of *ætiology* some progress is being made. Infection is thought to play a definite part and the evidence for this cited by Galloway (1905) was reinforced by Manson-Bahr (1915) and more recently by Leishman (1945), but convincing proof is still lacking. The importance of vitamin deficiency is evidenced by the cheilosis, glossitis, and by the response to treatment. Stannus (1942) showed that failure of phosphorylation might account for the faulty absorption of fat and of glucose, while Leishman (1945) has elaborated this interesting theory by suggesting that nicotinic acid and riboflavin, which occur in the body in phosphorylated form, are able to catalyse phosphorylation and that the process of intestinal bio-synthesis of vitamins is subject to gross interference by an infective agent. The relationship of sprue to pellagra is entirely fortuitous and there is no common *ætiological* factor. Chronic jejuno-ileal insufficiency as suggested by Bennett and Hardwick (1940) has a superficial attraction but does not help in elucidating the *ætiology*. Hurst (1942) put forward a theory that paralysis of the muscularis mucosæ leads to a loss of the pumping action of the villæ, but there is no acceptable evidence to support this suggestion. Radiological abnormalities have been much discussed but they require highly specialized interpretation and do not help either in elucidating the cause or in giving guidance as to correct treatment. The occurrence of macrocytic anæmia, even in the presence of gastric hydrochloric acid, suggests a failure of absorption of hæmatinic principle from the intestinal tract rather than a failure of production by the gastric mucosa. If it can be accepted that anæmia is a result only of failure of intestinal absorption of hæmatinic principle, Manson-Bahr's (1941) and de Langen and Lichenstein's (1936) recognition of the many parallel features of sprue and pernicious anæmia lose some of their significance, and the similarity of the two conditions becomes logical. Present evidence seems to point to a failure of the intestinal mucosa to perform its normal function of absorption and, if this one assumption proves to be correct, all the clinical manifestations of the syndrome are to be regarded as the direct result of this one derangement. The very rapid response to treatment points strongly to a disorder of function rather than of structure, but, for the time being, most of our ideas about the *ætiology* of this syndrome are based upon clinical observation unsupported by controlled experiment.

Stannus says: "There is a functional derangement of the bowel due to deficient fat absorption and not deficient fat absorption due to paralysis of the muscularis mucosæ of its wall."

This aspect requires further detailed investigation which should include comparative analysis of food intake and faecal output, and experiment to demonstrate, if possible, the

response of individual manifestations of deficiency to specific therapy. The low blood sugar curve is said by Thaysen (1929) to be due to some cause other than deficient absorption but further work on this aspect of the problem is required, and Thaysen's view may prove to be incorrect.

Response to treatment with certain liver extracts supports the probability of a factor of deficiency while the occurrence of sprue in minor local epidemics gives colour to the possibility of an infective agent. The great variety of diets advised in years gone by leads to the almost inescapable conclusion that none of them had any specific virtue and that all of them owed their partial success to a reduction of the fat content of the diet or simply to a reduction of bulk. Certain of the diets have a high vitamin content and in ancient times the Chinese already employed liver in the treatment of sprue.

Nevertheless, vitamins, when given by mouth, have no therapeutic effect and I have frequently observed that the largest doses of nicotinic acid are tolerated without either vasomotor or digestive disturbance on the one hand, or clinical improvement on the other. It is improbable that any of the diets formerly employed had any vitamin content of specific value in this syndrome, until intestinal absorption was restored to normal.

Treatment.—Keele and Bound (1946) writing from the Sprue Research Team, Poona, describe their treatment, which was designed only to make the patient fit to travel, under the following headings:

(1) Diet: The high protein, low fat, low carbohydrate diet of Fairley (1930, 1936) was adopted. A series of five diets compiled by Napier (1943) was used as a basis. The importance of constancy and regularity of diet was emphasized and increase was often followed by relapse. Nicotinic acid and sometimes riboflavine were added.

(2) Bed rest: This they regard as important.

(3) Parenteral liver they regard as unnecessary in most mild cases but "useful" in all severe cases.

I have quoted this recent paper as being, perhaps, typical of current opinion in this country but I would hasten to add that my own views are very different.

Rhoads and Miller (1934) and Castle and co-workers (1935) showed that the anaemia and other symptoms of sprue all respond to liver when given as a crude extract parenterally. This observation has been proved beyond any doubt and should be the basis of all modern treatment of this syndrome.

In 1939 there came under my care a merchant captain with the fully developed syndrome of sprue together with severe macrocytic anaemia. He was treated with high protein, low fat diet and large doses of anahæmin which is generally accepted as a liver extract of high anti-anaemic potency. The patient's blood picture made a rapid improvement but his general condition deteriorated and he died after about five weeks in hospital. Autopsy showed the classical picture of dehydration with visceral and intestinal atrophy.

Death from sprue is by no means uncommon in spite of a satisfactory blood picture and Manson-Bahr (1915) in his admirable monograph was already able to quote two such cases.

This single misfortune did something to destroy my belief in the value of diet and caused me to reconsider the place of parenteral liver therapy.

The next patient to come under my care was aged 70 and had had a previous attack of sprue two and a half years before with spontaneous remission. The stools were typical but her general condition was good. She had severe macrocytic anaemia. She was treated with intramuscular injections of Hapatex T and both her stools and blood picture quickly returned to normal although she continued to take full ward diet without any restrictions.

Since that time it has been my practice to allow all patients with sprue to take a full ward diet, and to get up when they wish. They receive crude liver injections in the form of Plexan 4 c.c. daily for one week, alternate daily for one week and twice weekly thereafter, and to this is added oral nicotinic acid 50 mg. t.d.s.

A single dose of nicotinic acid 150 mg. is given to test vasomotor and digestive reactions. So far no patient tested has complained of flushing before the beginning of treatment, while all patients have given a specific vasomotor response after treatment for two to three weeks. This observation supports the contention that crude liver quickly restores intestinal function. Nine consecutive patients have been treated in this way and the response in every case has been satisfactory. The average gain in weight has been 27 lb., varying from 13 lb. to 52 lb. Stools return to normal in about seven days and the only untoward phenomena have been pain at the site of injection and a transient oedema of the feet and legs, which generally appears in the second week, and may be due to sodium retention. Only one patient has relapsed and this only for a few weeks. Dr. Wilfrid Oakley has treated two patients in the same way. The

first, aged 29, gained 35 lb. in two months, while the second gained 31 lb. in four months and when last seen was a little troubled by constipation.

One patient similarly treated by another colleague has gained 29 lb. in five weeks with return of normal bowel function.

Two of my own patients call for particular comment. The first, a lady aged 51, recently home from India, presented the full syndrome of sprue with severe emaciation, and weighed only 74 lb. She had been on a fat-free diet and had had injections of liver of an unspecified brand.

She had only a moderate degree of anaemia. In October 1945 she was admitted and given the treatment already described of normal ward diet with injections of Plexan. Her weight to-day is 135 lb. or almost doubled. Figs. 1 and 2 are photographs of this patient taken before and after treatment.

November 4, 1945

FIG. 1.

April 2, 1946

FIG. 2.

The second patient on whom I should like to comment in more detail was first seen with the full syndrome by a colleague. He was treated with diet, vitamins by mouth and injections of Hepatex T. He was transferred to my care because his weight had not increased very much, and glossitis, cheilosis, and some looseness of the bowels had persisted. Oral nicotinic acid produced no reaction. He was then treated according to our present routine. The glossitis and cheilosis disappeared within a week, his moderate anaemia disappeared and he gained 9 lb. in weight in three weeks. After fourteen days, flushing occurred with 150 mg. of nicotinic acid.

The response of this small series of patients to crude liver injections has caused me to believe that diet is of little or no consequence in the treatment of sprue. It seems that there is a deficiency due to a functional disorder of intestinal absorption which can only be remedied by adequate parenteral therapy. With only two exceptions these patients have remained under prolonged observation, and in only one case has relapse occurred.

The response to Plexan may not be specific and I wish to imply no criticism of other branded liver extracts. Nevertheless it is highly probable that Plexan contains "impurities" which are of the highest value in the treatment of sprue. The next step must obviously be to try to identify the nature of the "impurity".

The active constituent contained in liver extract is not known but a plan has been devised which may eventually lead to its isolation, provided that patients become available for the work. It is possible that after heavy initial doses smaller and less frequent injections may prove sufficient for maintenance, and trial of this is now proceeding.

Comment.—I believe that there is now sufficient evidence to show that sprue is a deficiency disease possibly resulting in the first place from an intestinal infection. The subsequent course is conditioned by a functional disorder of the bowel which interferes with absorption of fat, carbohydrate and a hypothetical essential factor. Certain crude liver extracts contain a substance which restores the function of the bowel, and at the same time either permits vitamin absorption from the intestine by the process of phosphorylation or itself provides the missing factors.

The various fractions of the vitamin B₁₂ complex have been used at different times, both orally and parenterally. It is improbable that any of them have any specific

value in this syndrome, although their combined parenteral administration might be useful. Nevertheless crude liver is a potent source of vitamin B₂ complex and it is possible that an unidentified fraction may prove to be the specific factor. The search for this "S" factor must start from those crude liver extracts which undoubtedly contain it, and will not be complete until it has been chemically identified. At the present time only Plexan has given consistent therapeutic response in my hands but others are no doubt effective as in one of my cases treated with Hepatex T.

If these assumptions are correct planned research should lead to the isolation of the essential factor.

Sir Philip Manson-Bahr agreed entirely with Dr. Wingfield that liver injections afforded the best means of treating tropical sprue. The cruder the preparation the better; the most favourable results had been obtained with the Bayer product of Campolon, but since the war, with Plexan which was a similar preparation. Furthermore he agreed that large continuous dosage was necessary. For controlling the diarrhoea in the earlier stages of treatment he had recently used sulphaguanidine or sulphasuxidine in 10 to 12 grammes daily doses. He agreed that the appearance of the nicotinic acid reaction was probably a good indication of the restoration of normal absorption from the small intestine. It would undoubtedly be desirable to make further observations on this point.

Dr. H.-S. Stannus said that Dr. Wingfield, by emphasizing the importance of dosage in the treatment of sprue by crude liver extracts, had performed a valuable service. The treatment by large doses is not new, as he had stated, but the point had not always been recognized in the past and might be overlooked by younger men called upon to treat the disease.

Ideas concerning treatment should be bound up with ideas concerning pathogeny. Writing in 1942 he (Dr. Stannus) had brought forward evidence for believing that the failure in sprue lay primarily in deficient phosphorylation of fatty acids, the absorption of neutral fats being interfered with secondarily to a greater or less extent. In the latter case wasting is not a pronounced feature as in one of Dr. Wingfield's cases. The absorption of neutral fats and of fatty acids according to the "partition" theory of Alastair Frazer occurs by different methods, the two follow different paths with different destinations. This theory Dr. Stannus applied to sprue. Fatty acids are phosphorylated with the formation of phospholipids before absorption takes place, neutral fats are absorbed as a fine emulsion. One believes that in crude liver extract there is a factor which like other vitamins acts as a co-enzyme—united to a specific protein, the apoenzyme, it catalyses the phosphorylation of fatty acids in the bowel.

Wing Commander J. W. Paulley said that he had had the opportunity for a period of eighteen months of receiving cases of sprue invalided from the Eastern theatre of war. Efforts had been made at a careful analysis of these cases, and one of the most notable features of this analysis had been figures of preceding intestinal infection at a rate approximating to Sir Philip Manson-Bahr's figure of 40-5% but being higher than the published figures of Leishman, and those of Keele and Bound.

Working in conjunction with Squadron Leader G. J. Aitken he had carried out nicotina-mide methochloride excretion tests in a small series of controls, of sprue, convalescent sprue and amoebiasis. The method used was that of Coulson, Ellinger and Holden (*Biochem. J.*, 1944, 38, ii, 150), and of Ellinger Benesch and Hardwick (*Lancet*, 1945 (ii), 197). The result of these investigations showed, as far as they went, a deficient excretion in cases of sprue, even though the latter had been totally free of symptoms for three months or more, and also in amoebiasis, though the majority of the latter were not suffering from intestinal "hurry".

He mentioned these rather unexpected, though unconfirmed findings, in the discussion for what they were worth.

Dr. W. E. Cooke said that recently he had sent a patient to Dr. Wingfield who had only improved slowly on Hepatex but whose improvement on Plexan was remarkable.

Dr. Wingfield's statement that patients with sprue were put on full ward diet on admission to hospital was a practice that was not free from danger for in some patients perforation might occur. Sir Philip Manson-Bahr would concur with him that they had seen this happen.

Dr. Wingfield (in reply): I am glad to find so large a measure of agreement as to the need for large doses of crude liver. It is to be hoped that this treatment will be generally employed. The possible dangers of full diet are appreciated and in several emaciated patients a few days of milk and egg diet is needed before progress to unrestricted dietary is ordered.

DISCUSSION ON RHINOLOGY IN THE MEDITERRANEAN AND AFRICAN AREAS

J. P. Stewart: I was responsible for the ear, nose and throat work in a British General Hospital at Teheran during 1943 and it was from that source that the material for this paper comes. The climatic and hygienic conditions are so intimately bound up with the infection of the paranasal sinuses, that I will briefly outline their main features. The southern half of Persia is mostly composed of arid barren desert. The summers are very hot with hardly a cloud visible in the sky and with a temperature of as much as 130° F., while the winters, though of short duration, are very cold with a temperature just above freezing point or even below zero. The rainfall is scanty even in winter. The annual fall in Teheran is 9.53 inches, so that the humidity is exceedingly low. For four months in the summer a constant dust-laden wind, which is called the Shamal, blows from the North West. Whirlwinds wherein columns of dense dust and small stones are caught up, and going by the name of "dust devils" or "whirligigs", suddenly arise and tear through space drenching with dust everything and everybody in their erratic course. Sanitation is extremely rudimentary and much of the human excreta is deposited in open spaces. The sun bakes the excreta and in a very short space of time it disintegrates, becomes pulverized, and is blown about in the dust. There is no piped water from reservoirs and the water supply is obtained from open streams and if I describe the water supply of the capital city, Teheran, it will give an idea of the primitive conditions of such a supply. The main water supply is derived from the streams which run down from a mountain range some 10 miles distant and those streams often pass through some small villages in their course. Short of the city these streams are directed into open artificial channels and then led into the city to be diverted into large gutters with an earth or cement base which run down the principal streets. One does not need a great stretch of imagination to visualize the indignities to which this water supply is subjected to during its course through the city. Swimming pools were filled from the open supply but the water was taken off from as far out from the city as possible and they were, when under military supervision, heavily chlorinated. Despite the heavy chlorination many cases of paranasal sinus infection arose from these swimming pools as no doubt the heat of the water and the exceptional number of people using the pool contributed in no small measure to the infectivity obtaining in it. In the field, water was scarce and the best of it was taken for drinking purposes so that practically any other source of supply was used for washing. The British Tommy when washing invariably threw handfuls of water on to his face some of which would enter the nasal cavities and it was quite a common practice for him to sniff water into the nose and then expectorate it as this moistened his dry nose and washed the dust and grit out of it. It can readily be appreciated that infection of the nasal cavities might thus take place by the introduction of infected water.

Locomotion was by motor transport and a column on the move was shrouded in a thick dust pall which coated the individual from head to foot and irritated the upper air passages beyond measure, and one's expectoration was black with grit and dust.

During the ten months 896 ear, nose and throat cases passed through my Department and 303 suffered from an affection of the external or internal nose. 154 (51%) of those cases were due to an infection of one or other of the paranasal sinuses. The maxillary air sinuses were affected either uni- or bilaterally in 106 cases, the frontal sinuses

similarly in 8 cases, and a combination of these two sinuses in 8 cases, the ethmoid cells in 30 cases and a pansinusitis occurred in 2 cases. A preliminary X-ray examination of the sinuses was made in every case, and a proof puncture was performed to confirm the radiological findings in cases of suspected maxillary antrum infection. In 40 cases the returning fluid from the antral wash-out was clear or had shreds of mucus in it but there was a varying amount of resistance to the irrigating fluid thus demonstrating a swollen antral mucosal lining. A further 21 cases yielded mucopus while in 54 cases frank pus was washed out, generally in copious quantity.

This high incidence of every second case suffering from nasal sinus disease was mainly due to climatic and hygienic factors. The intense heat of very low humidity dried up the natural secretions of the nasal mucosa causing the mucous membrane to become congested, dry and glazed. Infected dust was then inhaled, which impregnated this irritable membrane thus opening up the pathways of infection. When infection became established and an exudate formed, it too was dried up and formed a cake or crust which retarded further drainage from the deeper structures and in fact sealed them off. Much the same sequence of events was produced by infection which was water-borne though dust was by far the most frequent infecting agent. A number of cases gave a history of a previous attack of nasal sinusitis which, though it had cleared up, recurred readily under the conditions described.

The treatment of those cases of nasal sinus disease, which took place in the penicillin era, did not differ from that employed elsewhere. There was little contra-indication to operation but one had to be on the outlook for signs of heatstroke and heat exhaustion especially if there was much loss of blood, post-anæsthetic vomiting, or indeed any marked dehydration of the tissues. If the patient had suffered from a previous attack of malaria, operation often precipitated another attack giving rise to a high temperature which was rather worrying until the cause of it was ascertained, therefore a blood slide was taken as a routine from all cases which ran a temperature following operation. 42 cases were operated upon—31 radical antrum operations, 1 intranasal antrum drainage, 4 external frontal sinus, 1 intranasal frontal sinus drainage and 5 ethmoidectomies were performed.

The post-operative results were rather disappointing but I believe that if penicillin had been available those results would have been much more satisfactory. The sulphonamides did not prove of great value in promoting healing. Recovery was retarded mainly because of a constant reinfection of the raw areas. The operation cavities continued to suppurate for a long time so that it became necessary to advise, in the majority of cases, evacuation to a more equable climate.

In the course of time our experience taught us to operate less and less on this type of infection and any marked case of sinusitis was at once recommended for evacuation.

R. B. Lumsden (Abridged): Climate.—Except for a narrow belt along the Mediterranean shore, where 8 to 12 in. of rain falls in the winter months only, Egypt is almost rainless. At Alexandria, the mean maximum temperature is 99° F.; while 130 miles inland at Cairo, where the proximity of the desert begins to be felt, it is 110° F. At Cairo the mean relative humidity in summer is about 45% and in winter about 70% (Encycl. Brit.). There are periods, however, especially in spring, but also in autumn and summer, when this is much lower. These periods occur during the "khamsin"—a dusty, sand-laden wind which blows off the desert for several days on end, during which the temperature is high and the air extremely dry. These "khamsins" also occur in Palestine, where hot, dry summers are experienced, but where, unlike Egypt, there is a heavy winter rainfall.

Sinusitis.—During the year 1944, the total number of ear, nose and throat cases seen throughout the Command was 27,816, of which 6,105 (22%) were nasal cases. Of these, 834 (13.7%) were admitted to hospital on account of sinusitis; 347 (5.7%) being chronic and 487 (8%) acute (see Table). Unfortunately consolidated records do not provide

MIDDLE EAST FORCE, 1944 (ALL HOSPITALS).

Total number of ear, nose and throat out-patients	27,816
Total number of nasal cases	6,105
Total number of nasal cases	6,105
Total number of throat cases (excluding acute tonsillitis)	3,337
Total number of laryngeal cases	656
Negative examinations	2,627

Cases admitted to hospital on account of sinusitis—	834	13.7% of all nasal cases
(a) Chronic	347	5.7% of all nasal cases
(b) Acute	487	8% of all nasal cases

figures relating to individual sinuses, nor do they afford any detailed statistical information concerning out-patient cases. Collins (1943), in Cairo, found that 20.3% of his total

out-patients and 66.8% of nasal cases suffered from sinus infection, but these figures appear to be high for the Middle East as a whole. Many of my own figures were unfortunately lost in transit.

Concerning *treatment*, Collins (1943) found that 74% of his sinus cases yielded to conservative measures, which included repeated proof puncture. There was general agreement with his plea for conservative methods. As after all nasal operations, convalescence was slower than at home and final operative results were, on the whole, less satisfactory. It appears that the penalties of interference with the nasal mucous membrane are infinitely greater in a hot, dry climate.

Seasonal incidence: At the top of the chart are shown the quarterly figures of (1) all ear, nose and throat out-patients, (2) out-patient nasal cases, and (3) ear, nose and throat hospital admissions throughout the Command; from October 1943 to December 1944. The general downward trends are an indication of a general reduction in the population. In the lower half of the chart the interrupted line shows the number of *admissions* to hospital on account of *chronic* sinusitis, and it will be observed that the seasonal incidence was fairly constant. The upper line relates to admissions on account of *acute* sinusitis and shows an appreciable summer rise. A similar incidence was observed in respect of less severe cases treated as out-patients.

Undoubtedly, many cases of sinusitis were related to swimming in fresh water pools (Collins, 1943; Lumsden, 1945); and resolution was generally slow. In South Iraq, on the other hand, Reeves (1943) comments on the small number of cases of acute sinusitis admitted during the dusty summer months. He found that the large majority occurred in the cold weather. It is to be noted that 48% of his patients were Indians.

There was general agreement with Collins (1943) concerning the frequency of frontal headache associated with sinus tenderness, and redness and frequently dryness of the mucosa of the middle turbinate. This condition occurs most frequently during the hot, dusty "khamsin" winds already mentioned and is most common in Egypt, where "khamsins" are associated with a much dustier atmosphere. As Collins has pointed out, while an allergic factor may be present, clinically it does not resemble vasomotor rhinitis. The diagnosis of acute frontal sinusitis was generally applied to these cases, but there would appear to be some justification for regarding the condition as that of "vacuum" sinus headache. Colleagues who served in different parts of the Middle East corroborate the opinion that this condition seldom occurs near the sea and Daggett informs me that

similarly in 8 cases, and a combination of these two sinuses in 8 cases, the ethmoid cells in 30 cases and a pansinusitis occurred in 2 cases. A preliminary X-ray examination of the sinuses was made in every case, and a proof puncture was performed to confirm the radiological findings in cases of suspected maxillary antrum infection. In 40 cases the returning fluid from the antral wash-out was clear or had shreds of mucus in it but there was a varying amount of resistance to the irrigating fluid thus demonstrating a swollen antral mucosal lining. A further 21 cases yielded mucopus while in 54 cases frank pus was washed out, generally in copious quantity.

This high incidence of every second case suffering from nasal sinus disease was mainly due to climatic and hygienic factors. The intense heat of very low humidity dried up the natural secretions of the nasal mucosa causing the mucous membrane to become congested, dry and glazed. Infected dust was then inhaled, which impregnated this irritable membrane thus opening up the pathways of infection. tion, but I should guess I served upwards of 25,000. For the most part these men were engaged in clerical work, or in maintenance of supplies to the various theatres of war.

The contrast between my Service patients and the few natives I saw was striking. I think a laryngologist requires an educated patient, if he is to give of his best, but with the natives I saw it was obvious that no amount of explanation or of reason would be of use. They required a quick and dramatic form of treatment, and a promise of absolute cure.

In the last few months of my appointment I went to Palestine once a week to visit the R.A.F. Hospital near Tel Aviv. It is suggestive for the future that I began my clinic there at 9.30 in the morning, having already travelled 250 miles by air from Cairo. I returned to Cairo the same evening, having seen between 20 and 30 out-patients, and this I did regularly each week.

Cairo was a surprise to me, as I think it is to most Englishmen. It is an ancient city which has never been sacked, nor has it been destroyed by fire. The present city certainly dates back to the Romans and the streets are now some 40 ft. above the floor level of the old Coptic churches. There is no rain and the dust cloud is continuous, so much so that the sun never tans the skin in the city and the suburbs. Most of my patients were quartered in or near the city and I am sure the atmosphere was a cause of the infections of the nose and throat.

The desert was healthier and I was often told that symptoms of sinus infection were less troublesome there. The weather too had much to do with the number of cases seen, but it is easier to be sure of the weather as a factor, as infections varied so obviously with the seasons. The Nile rises in mid-June and it is at this time that cases of sinus infection are seen in greatest numbers.

In Cairo antral infection rises steadily to a peak in July, when we had to set aside two mornings for antral lavage alone. I will describe results of treatment later, but by the expression antral infection, I include all cases where the infection of the antrum is the controlling factor, although other sinuses may be involved.

I think antral infections are more common in the Services generally than they are amongst civilians and a possible reason is the fact that a number of people live and work in close contact. In Cairo, at all events, the outdoor bathing pools were responsible for a number of sinus infections. Everyone bathed in Cairo and bathing is possible for nine months in the year. The pools were used every day and in most cases all that could be done was to empty them, and chlorinate them overnight. They were, in fact, only empty for an hour or two during the night. So many patients came with a history which began after bathing, that it was obvious that there was some relation, but while it was clear that the swimming pools made the infection worse, it was still possible that the infection had already been planted in the nose.

These cases were admitted with the usual signs of an acute sinusitis. If they improved with rest and inhalations I did not wash the antrum out, but this was often necessary. If the infection was overcome in this way, there was no difficulty, but the chief problem was the subacute or recent case which did not improve.

However, an antral infection which has not improved with lavage and rest is not enough to justify repatriation, and it was my experience that transfer to another Middle East climate, such as Palestine, did little good. I think many would have recovered in England, but I could not send them home for this reason.

This will explain, I hope, the number of operations for acute and subacute sinusitis. Where the history was longer than six months, and there was no improvement after the antrum had been washed out six times, an antrostomy was performed. The results were fairly good; certainly equal to what I would expect in England.

It is curious that recovery from operation is as good in Cairo as it is in England, even in hot weather. There were few complications: the alveolar incision in a Caldwell-Luc antrostomy perhaps became more readily infected, and certainly closed more slowly, sometimes taking three months. The worst complication I saw was infection of the fat of the cheek following a Caldwell-Luc antrostomy, and subsequent slow separation of the slough. There was one death, in an officer who had a recent infection, and who was recommended for operation because he held a key position in the Middle East. He developed an acute pancreatitis, and later died from an empyema.

Two interesting cases were two young Australians, both referred with bronchiectasis and antral infection. Both these men had only been a few months in the Middle East, and had never had either sinus or chest symptoms before. After this, I looked carefully

he did not encounter such cases in Malta, where the climate remains humid throughout the year.

A series of laboratory experiments on rabbits has been carried out by Rosedale (1944) concerning effects of temperature and humidity on sinusitis. He found that a relatively cool and dry atmosphere was the most beneficial, while a hot and relatively dry atmosphere was the most harmful.

Though in several respects not strictly comparable, reports in recent literature suggest that the incidence of sinusitis is considerably higher in Egypt (Collins, 1943) than at home (Birrell, 1944), and that it is slightly higher at home than in North Africa (Birrell, 1944) and Iraq (Reeves, 1943).

Deviations of the septum: It was found, as in sinusitis, that patients who gave a history of mild symptoms of nasal obstruction at home frequently sought advice because these symptoms had become more marked and persistent after going abroad.

Atrophic rhinitis was encountered infrequently. Severe cases presumably were not sent overseas. The cases seen gave a history of relatively mild symptoms at home, but found summer conditions, especially in desert districts, quite intolerable and these had to be sent home.

In spite of the frequency and severity of *diphtheritic infections*—both faucial and cutaneous—nasal infection was very rarely encountered.

Leprosy was never seen in European Service personnel.

Nasal allergy.—True *pollen allergy* was judged to be comparatively uncommon and symptoms are of short duration. A number of people were encountered who suffered from hay fever at home, but did not experience seasonal symptoms in these regions. On the other hand, an appreciable proportion of the forces experienced mild symptoms of perennial *vasomotor rhinitis*. One frequently heard people commenting on their nasal stiffness and watery discharge, though only a relatively small proportion suffered enough inconvenience or discomfort to warrant seeking advice. Symptoms were accentuated during “khammins” and showed no appreciable tendency to diminish, even after long periods of residence, while, by way of contrast, it was observed that otitis externa took a much heavier toll of fresh arrivals than of those who were thoroughly acclimatized. Many of the severer cases gave a history of suffering from hay fever or mild perennial symptoms at home and these people were not prone to develop the dry nose with so-called “vacuum” sinus headache, so that an excessively moist nose affords a compensatory safeguard against this condition. The absence of this condition among African native troops was noted, though it occurs among the Egyptian population.

Finally, some advice concerning patients who propose to proceed to this part of the world:

(1) Sufferers from *nasal affections* need not be dissuaded from spending the winter in Egypt. On the other hand, they should be discouraged from believing that their condition will benefit materially therefrom.

(2) Sufferers from chronic or recurrent acute sinusitis should be advised against spending the spring, summer or autumn months in any of the Middle East countries.

(3) Persons afflicted with true *pollen allergy* may escape the acute discomfort of the hay fever season at home, but they cannot confidently expect to enjoy complete freedom from all nasal symptoms.

(4) *Vasomotor rhinitis* is unlikely to be relieved and might be aggravated.

William McKenzie: I was posted to Cairo from India in June 1943. The war by that time had left Cairo behind, and the nearest battle front was 1,000 miles away. The only active combatants in my area were the few pilots who undertook the exceedingly dangerous duties of photographic reconnaissance. I do not think my work differed much from work in peacetime in the Cairo area, if allowances are made for the greater likelihood of the spread of infection in barracks: there were of course large numbers of the Royal Air Force in the area; how many I never found out, as this was secret informa-

tion, but I should guess I served upwards of 25,000. For the most part these men were engaged in clerical work, or in maintenance of supplies to the various theatres of war.

The contrast between my Service patients and the few natives I saw was striking. I think a laryngologist requires an educated patient, if he is to give of his best, but with the natives I saw it was obvious that no amount of explanation or of reason would be of use. They required a quick and dramatic form of treatment, and a promise of absolute cure.

In the last few months of my appointment I went to Palestine once a week to visit the R.A.F. Hospital near Tel Aviv. I returned to Cairo the same evening, having seen between 20 and 30 out-patients, and this I did regularly each week.

Cairo was a surprise to me, as I think it is to most Englishmen. It is an ancient city which has never been sacked, nor has it been destroyed by fire. The present city certainly dates back to the Romans and the streets are now some 40 ft. above the floor level of the old Coptic churches. There is no rain and the dust cloud is continuous, so much so that the sun never tans the skin in the city and the suburbs. Most of my patients were quartered in or near the city and I am sure the atmosphere was a cause of the infections of the nose and throat.

The desert was healthier and I was often told that symptoms of sinus infection were less troublesome there. The weather too had much to do with the number of cases seen, but it is easier to be sure of the weather as a factor, as infections varied so obviously with the seasons. The Nile rises in mid-June and it is at this time that cases of sinus infection are seen in greatest numbers.

In Cairo antral infection rises steadily to a peak in July, when we had to set aside two mornings for antral lavage alone. I will describe results of treatment later, but by the expression antral infection, I include all cases where the infection of the antrum is the controlling factor, although other sinuses may be involved.

I think antral infections are more common in the Services generally than they are amongst civilians and a possible reason is the fact that a number of people live and work in close contact. In Cairo, at all events, the outdoor bathing pools were responsible for a number of sinus infections. Everyone bathed in Cairo and bathing is possible for nine months in the year. The pools were used every day and in most cases all that could be done was to empty them, and chlorinate them overnight. They were, in fact, only empty for an hour or two during the night. So many patients came with a history which began after bathing, that it was obvious that there was some relation, but while it was clear that the swimming pools made the infection worse, it was still possible that the infection had already been planted in the nose.

These cases were admitted with the usual signs of an acute sinusitis. If they improved with rest and inhalations I did not wash the antrum out, but this was often necessary. If the infection was overcome in this way, there was no difficulty, but the chief problem was the subacute or recent case which did not improve.

However, an antral infection which has not improved with lavage and rest is not enough to justify repatriation, and it was my experience that transfer to another Middle East climate, such as Palestine, did little good. I think many would have recovered in England, but I could not send them home for this reason.

This will explain, I hope, the number of operations for acute and subacute sinusitis. Where the history was longer than six months, and there was no improvement after the antrum had been washed out six times, an antrostomy was performed. The results were fairly good; certainly equal to what I would expect in England.

It is curious that recovery from operation is as good in Cairo as it is in England, even in hot weather. There were few complications: the alveolar incision in a Caldwell-Luc antrostomy perhaps became more readily infected, and certainly closed more slowly, sometimes taking three months. The worst complication I saw was infection of the fat of the cheek following a Caldwell-Luc antrostomy, and subsequent slow separation of the slough. There was one death, in an officer who had a recent infection, and who was recommended for operation because he held a key position in the Middle East. He developed an acute pancreatitis, and later died from an empyema.

Two interesting cases were two young Australians, both referred with bronchiectasis and antral infection. Both these men had only been a few months in the Middle East, and had never had either sinus or chest symptoms before. After this, I looked carefully

for evidence of bronchiectasis as a complication of sinus infection in Cairo, but with no result.

If antral infection is common in Cairo, there is one condition which is rare compared with civilian life, and that is vasomotor rhinitis or vagotonia. I can say definitely that this condition was seldom seen compared with the incidence in a London clinic to-day.

Table I gives the numbers of cases of antral infection seen in Cairo, and the result of treatment.

Operation was of course only undertaken after failure of lavage, and in the acute and recent cases both lavage and operation were avoided.

A comparison with infections in Palestine is given in Table II. The number of patients is less altogether, but the danger from bathing was less, as it was scabathing for the most part. There is an increase, however, compared with England, and this I think must be due to the climate of the Mediterranean area generally.

Operation	1						

R. Scott Stevenson spoke of his experience on Gibraltar, where he found a large amount of vasomotor rhinitis in people coming out from England who encountered a completely new flora with new pollens. About two hundred W.R.N.S. were working there, many in tunnels which were driven from one side of the Rock to the other, and among these a good deal of nasal trouble was found, owing to the prevalence of limestone dust. He employed desensitization by Francis's method of the irritable nasal mucosa, which in most of the cases gave a great deal of relief. One girl never left off sneezing as long as she was working in the tunnel, and her trouble in this respect was so severe that she was actually going to be sent back to England because of persistent rhinitis; repeated treatment with the dull-red galvano-cautery, however, enabled her to stay on at Gibraltar. The climate of Gibraltar was good, and during the two years he was there no rain fell from May until late September, but during the actual rainy season in March and April the fall was heavy; the annual rainfall was from 25 to 35 inches. There was a double water supply on Gibraltar, fresh and salt, the use of fresh water being much restricted. All their bathing was in the sea, and he did not believe that sea-bathing made sinusitis any worse; he had found many more cases of sinusitis when stationed in the West of Scotland, where it was very wet; he could remember seeing ten or a dozen cases in his out-patient clinic there in a single day, but on Gibraltar, although sinusitis was seen, it was not nearly so common. When operation was necessary in chronic maxillary sinusitis, he nowadays invariably carried out a Caldwell-Luc operation, and his experience was that this operation was very effective; his routine method was first to carry out lavage on three occasions, and if the condition did not clear up then a Caldwell-Luc was done.

W. I. Daggett said that in the Central Mediterranean area where he was stationed the incidence of sinusitis was extremely low. During a period of two years and three months when British troops numbered about 24,000, he operated upon only three cases; on one of those cases he carried out a Caldwell-Luc operation. All the bathing was in the sea. One very common nasal complaint which he found in the garrison of Malta, where the circumstances were very trying, was functional nasal catarrh. A great number of the cases showed a mild anxiety state, and amongst such patients it was extremely

common to get patients who came along complaining that they were being "poisoned" by the catarrh they were swallowing.

C. A. Hutchinson said that he was interested in the apparent association of a state of high relative humidity with the inverse occurrence of chronic sinusitis. He had spent two years in West Africa where there was a very high temperature and an extremely high relative humidity, but chronic sinusitis in particular—and any form of sinusitis for that matter—was practically non-existent there, and the main ear, nose and throat work consisted of various forms of nasal and aural myiasis. He had also spent four years in Central India, where there was an extremely high temperature—for about six weeks of the year the shade temperature was 116° —and here again there was a fairly high relative humidity, except in the "hot weather", when it was very dusty. In that part of the world there was a certain amount of sinusitis, particularly of the chronic type, but its incidence was not unduly high. In Northern India and on the Frontier, where he had spent more than four years, one had again extremely fierce heat but absolute dryness throughout a long "hot weather", with a great prevalence of a dusty wind comparable to the "khamisin" mentioned by previous speakers. There he had found a very high incidence of chronic sinusitis, though during a brief "cold weather" a large number of acute antra were seen. The site of chronic sinusitis found in Northern India was mainly frontal and ethmoidal, necessitating operative intervention—and cases had done well. It seemed to him that there must be some inverse relation therefore between the degree of relative humidity and the amount of chronic sinus infection to be found in a particular area.

J. Angell James said that his experience in the Middle East extended only over five months, as the greater part of his time overseas was spent in Italy and North Africa. In Cairo, his experience was very much the same as that brought forward by Mr. Lumsden, except in so far as the seasonal incidence of acute sinusitis was concerned. He arrived there at the beginning of August, which was regarded as the peak period for sinus trouble. A moderate number of cases were seen during that month, and the numbers fell during September and October, but in November they increased again and during December there was an epidemic, with many more cases than were seen in the summer.

With regard to the treatment of these cases they were fortunate in having ample supplies of penicillin. Many of the cases cleared up with hospitalization and treatment with penicillin and sulphonamides, and ultra-short wave therapy. The symptoms disappeared within a week, and the cases were seen again at the end of a fortnight, and at the end of three weeks skiagrams were taken. Not more than 10% failed to respond. (Local chemotherapy was used for those that failed to clear up completely with systemic treatment.) He himself had suffered from a severe attack, but the active phase lasted only four days, and on the sixth he started work again. In two weeks his sinus skiagrams were again clear.

It was considered that cases showing gross ethmoiditis were not suitable for operation in hot and dry climates, so that with few exceptions only antral operations were performed, and there he always used the Caldwell-Luc method, because his experience was that the cases which did not respond to local chemotherapy invariably had polypi or gross thickening of the mucosa in the antrum. Mr. McKenzie had mentioned the relatively small number of cases of allergic rhinitis seen in Egypt; at home he thought that 10% of all out-patients had some allergic signs, but in Egypt not more than 2% showed them.

J. A. Kilpatrick said that his experiences were very similar to those of Mr. Lumsden. The water in Egypt was definitely over-chlorinated, resulting in his own case in a stinging of the eyes which went on to conjunctivitis, wholly due, in his opinion, to the amount of chlorine in the water. He felt that probably the additional chlorine had an effect on the nasal mucosa, giving any organisms present an easier task. He had gone on to Malta from Egypt, and there he had an acute frontal sinusitis and recovered only after five weeks.

B. S. Carter said that he had been very much impressed in the Middle East, and even more so in Madagascar, with the high incidence of sinusitis in the South African troops. He was even more surprised to find how many of these South African troops had previously had radical surgery. The Caldwell-Luc operation seemed to have been carried out in South Africa on a much more extensive scale than in this country. As a rule, these cases seemed to do badly, but how much was due to a functional element he did

for evidence of bronchiectasis as a complication of sinus infection in Cairo, but with no result.

If antral infection is common in Cairo, there is one condition which is rare compared with civilian life, and that is vasomotor rhinitis or vagotonia. I can say definitely that this condition was seldom seen compared with the incidence in a London clinic to-day.

Table I gives the numbers of cases of antral infection seen in Cairo, and the result of treatment.

Operation was of course only undertaken after failure of lavage, and in the acute and recent cases both lavage and operation were avoided.

A comparison with infections in Palestine is given in Table II. The number of patients is less altogether, but the danger from bathing was less, as it was seabathing for the most part. There is an increase, however, compared with England, and this I think must be due to the climate of the Mediterranean area generally.

[illegible]

R. Scott Stevenson spoke of his experience on Gibraltar, where he found a large amount of vasomotor rhinitis in people coming out from England who encountered a completely new flora with new pollens. About two hundred W.R.N.S. were working there, many in tunnels which were driven from one side of the Rock to the other, and among these a good deal of nasal trouble was found, owing to the prevalence of limestone dust. He employed desensitization by Francis's method of the irritable nasal mucosa, which in most of the cases gave a great deal of relief. One girl never left off sneezing as long as she was working in the tunnel, and her trouble in this respect was so severe that she was actually going to be sent back to England because of persistent rhinitis; repeated treatment with the dull-red galvano-cautery, however, enabled her to stay on at Gibraltar. The climate of Gibraltar was good, and during the two years he was there no rain fell from May until late September, but during the actual rainy season in March and April the fall was heavy; the annual rainfall was from 25 to 35 inches. There was a double water supply on Gibraltar, fresh and salt, the use of fresh water being much restricted. All their bathing was in the sea, and he did not believe that sea-bathing made sinusitis any worse; he had found many more cases of sinusitis when stationed in the West of Scotland, where it was very wet; he could remember seeing ten or a dozen cases in his out-patient clinic there in a single day, but on Gibraltar, although sinusitis was seen, it was not nearly so common. When operation was necessary in chronic maxillary sinusitis, he nowadays invariably carried out a Caldwell-Luc operation, and his experience was that this operation was very effective; his routine method was first to carry out lavage on three occasions, and if the condition did not clear up then a Caldwell-Luc was done.

W. I. Daggett said that in the Central Mediterranean area where he was stationed the incidence of sinusitis was extremely low. During a period of two years and three months when British troops numbered about 24,000, he operated upon only three cases; on one of those cases he carried out a Caldwell-Luc operation. All the bathing was in the sea. One very common nasal complaint which he found in the garrison of Malta, where the circumstances were very trying, was functional nasal catarrh. A great number of the cases showed a mild anxiety state, and amongst such patients it was extremely

Tomography in the Diagnosis of Lung Carcinoma

By J. BLAIR HARTLEY, M.D., F.F.R. D.M.R.E.

THE diagnosis of chest lesions, and particularly as between primary carcinoma of the lung, primary mediastinal tumour, and mediastinal metastasis, frequently proves exceedingly difficult, and is sometimes impossible. Yet, as the possibilities of cure or alleviation by surgery or radiotherapy increase, early diagnosis becomes the more imperative. Both of these increasingly effective weapons demand accuracy in the final differential diagnosis; the former to decide the question of operability and the latter to enable radiation dosage to be planned, and the case marked down for full treatment or palliative dosage, or dismissed as unsuitable for either type of treatment.

From the radiotherapeutic viewpoint it is necessary not only to make the diagnosis but to prove it; not only to establish that the lesion is present but to demonstrate its depth and extent. None of the older methods enabled all these points to be established, and even a combination of radiography, bronchography and bronchoscopy could fail in one particular or more.

The diversity of appearances presented in carcinoma of lung or in mediastinal tumour makes radiological diagnosis from routine films difficult, and intensive study of proved cases and careful attention even by means of an efficient follow-up system fail to supply the student with any trustworthy memory-pictures with which to build up a mind-picture of either. This is due in part to the simulation of the one condition by the other, in part to the failure of bronchoscopy to demonstrate or prove by biopsy the existence of carcinomas in the less accessible bronchi or of those not within the bronchial lumen; and in part to the fact that so few cases actually die in hospital and thus come to post-mortem. Furthermore, these methods of investigation either fail in, or are unsuited to the re-examination of cases which have been subjected to radiation therapy.

The following table reveals that from 1940 to 1944 the number of cases of primary carcinoma of the lung referred for treatment each year had multiplied 3.3 times, whilst the number of cases with malignant disease of the mediastinum had multiplied 2.5 times. Note also that the cases listed as "not treated, too advanced", in the carcinoma of lung group, increased strikingly during this period. The total number of cases occurring in

not know. In Madagascar there seemed a tendency to a great deal of functional complaint. People came along saying that their sinuses were unsatisfactory and on examination one felt that further surgery was contra-indicated; they did not seem to improve on ordinary conservative measures, and a number had to be invalidated back to South Africa. His own experience of the climate of South Africa was just a passing one, but he supposed that it was rather drier than in England, and it did appear to him that the South Africans were more prone to the symptoms of chronic sinusitis.

T. B. Jobson said that he recalled a large number of such cases being in the hospital at Cairo in the war of 1914-18, and he remembered receiving a chit from headquarters asking him "if his operations were really necessary". It appeared that a slight deviation of the septum which in this country caused no particular trouble changed its character in Egypt, and became the cause of a good deal of complaint. At all events he had a large number of men who had not a very marked deviation who in Egypt made the complaint of inability to breathe properly.

The President said that one interesting statement was that sinus infection was more common in areas where living quarters were close, suggesting that sinus trouble was infectious. Possibly it was, but one wondered what happened in slum quarters where living conditions were worse than in crowded camps.

J. Angell James, in reply to a question by the President, said that the cases he had mentioned were diagnosed on clinical and radiological signs and followed up radiologically afterwards. (Swabs were taken before embarking on penicillin treatment.) Proof puncture was not performed except in cases that failed to respond, because he did not consider it advisable to puncture sinuses during the early stages of acute sinusitis.

R. B. Lumsden agreed that little or no trouble was experienced from sea bathing and that chlorination of fresh water swimming pools might be a precipitating cause of sinus infection. In a warm climate, people indulge in swimming while suffering from colds; this might aggravate an infection already present in the nose. He himself suffered from hay fever at home, but except for one week, while living with orange groves around him, he never suffered from hay fever in the Middle East. The operation figures he had given were the collective figures of all the surgeons in the Command.

J. P. Stewart, in reply to a question, said that it was quite impossible to make any comparison between the intra- and extra-nasal operations on the antrum in this series because only one intranasal drainage was carried out as against 31 extranasal operations. He was in complete agreement with Dr. Scott Stevenson's remarks as to the positive value of the Caldwell-Luc operation.

William McKenzie said that he had not found the number of septum operations to be higher in Cairo than in England, and he had never performed a submucous resection in candidates for air crew, in the absence of symptoms on the ground.

Tomography in the Diagnosis of Lung Carcinoma

By J. BLAIR HARTLEY, M.D., F.F.R. D.M.R.E.

THE diagnosis of chest lesions, and particularly as between primary carcinoma of the lung, primary mediastinal tumour, and mediastinal metastasis, frequently proves exceedingly difficult, and is sometimes impossible. Yet, as the possibilities of cure or alleviation by surgery or radiotherapy increase, early diagnosis becomes the more imperative. Both of these increasingly effective weapons demand accuracy in the final differential diagnosis; the former to decide the question of operability and the latter to enable radiation dosage to be planned, and the case marked down for full treatment or palliative dosage, or dismissed as unsuitable for either type of treatment.

From the radiotherapeutic viewpoint it is necessary not only to make the diagnosis but to prove it; not only to establish that the lesion is present but to demonstrate its depth and extent. None of the older methods enabled all these points to be established, and even a combination of radiography, bronchography and bronchoscopy could fail in one particular or more.

The diversity of appearances presented in carcinoma of lung or in mediastinal tumour makes radiological diagnosis from routine films difficult, and intensive study of proved cases and careful attention even by means of an efficient follow-up system fail to supply the student with any trustworthy memory-pictures with which to build up a mind-picture of either. This is due in part to the simulation of the one condition by the other, in part to the failure of bronchoscopy to demonstrate or prove by biopsy the existence of carcinomas in the less accessible bronchi or of those not within the bronchial lumen; and in part to the fact that so few cases actually die in hospital and thus come to post-mortem. Furthermore, these methods of investigation either fail in, or are unsuited to the re-examination of cases which have been subjected to radiation therapy.

The following table reveals that from 1940 to 1944 the number of cases of primary carcinoma of the lung referred for treatment each year had multiplied 3.3 times, whilst the number of cases with malignant disease of the mediastinum had multiplied 2.5 times. Note also that the cases listed as "not treated, too advanced", in the carcinoma of lung group, increased strikingly during this period. The total number of cases occurring in

the area served by this hospital (Christie Hospital and Holt Radium Institute, Manchester) must be still greater, for this table includes few early cases, since these are very largely filtered out by the thoracic surgeon (Mr. Graham Bryce).

TABLE I.—ANALYSIS OF CASES OF MALIGNANT DISEASE OF THE LUNG AND MEDIASTINUM REFERRED TO THE HOLT RADIUM INSTITUTE, 1940-1944.

Year	Total No. referred	Malignant disease of lung			Total No. referred	Malignant disease of mediastinum		
		No. treated by radio- therapy	No. not treated			No. treated by radio- therapy	No. not treated

1944	110	56	54	—	25	18	6	1
	Total 408	249	140	19	81	63	14	4

My predecessor, the late E. W. Twining, was one of the first of British radiologists to recognize the value of tomography in chest examinations, and it was his original "simple attachment to the Potter-Bucky couch" which I have used throughout these investigations. (Photographs of Twining's apparatus were shown on the screen.) It continues to function satisfactorily and has required no modification beyond re-calibration, when it was found to be "recording" a stratum or plane 1.0 cm. above that actually shown on the tomograms; probably an error in the original calibration.

Of its limitations and disadvantages I am aware—the table-top is a curved one, the tube-travel is inevitably in the long axis of the chest, and the tube does not tilt but simply passes over the chest as the film passes in the reverse direction under it—but the point to be emphasized is that this apparatus has provided tomograms, which, examined critically over a number of years, have proved of great value both to diagnostician and to radiotherapist.

My claims in respect of the values of this method of examination, being based on the analysis of information obtained by the use of a primitive tomographic unit, are probably an understatement of values rather than an overstatement.

Technique.—This has been limited by the fact that the table-top is curved. There is no doubt that the flat-topped table is essential for radiology.

Focus-table distance was 36 in. Table-top to film distance was 13¼ in. Length of tube shift 12 in. to 15 in. Film shift varied between 2 in. and 3¾ in. The patient was usually supine: thus the tube-shift was traversing the long axis of the patient.

Exposure: constant 100 mA. for average of two seconds. No cone was used. In place, a lead diaphragm was inserted, with an aperture in its centre calculated and cut by the Physics Department, sufficient to enable the emergent beam to cover whatever size of film was to be used. Thus, three filters were in use, for 15 in. by 12 in., 12 in. by 10 in., and 10 in. by 8 in. films respectively.

In depicting the bronchi, tomograms were obtained at planes 1 cm. apart, the usual levels being those at 9, 10, 11 and 12 cm. (or 10, 11, 12 and 13 cm.) from the table top. The extreme levels used were at 8 cm. and 14 cm. respectively.

Each tomogram was identified by the use of a lead number indicating the height-above-table-top of the plane or section.

Thus, particularly in dealing with small or localized lesions likely to be irradiated, the depth of the centre of the lesion was rapidly established, whilst the limits of the lesion were delineated, although with a lesser degree of accuracy.

The demand for tomography arose in the Holt Radium Institute chiefly for the following reasons:

First because the established diagnostic method of bronchography using lipiodol was contra-indicated, the therapists objecting on the grounds that treatment was already sufficiently difficult without introducing the factor of an unknown quantity of iodine within the lung.

Secondly there was the necessity to localize the treatable lesions in depth and if possible in extent.

Thirdly it was recognized that bronchoscopy was of limited value in that not all carcinomas (obstructive or otherwise) lie in situations visible or reachable by the bronchoscope. Thus bronchoscopy was helpful if it produced a positive finding and/or a positive biopsy result; but it was valueless if it afforded only a negative report and/or a negative biopsy, or an indeterminate one.

Lastly, wartime conditions made imperative exact and rapid reviews of individual case problems.

Value of tomography.—Tomography though not, in itself, a diagnostic method, is, nevertheless, of great diagnostic value. It has been shown to be exceedingly accurate in the demonstration of carcinoma within or deforming the walls of the bronchi. Lesions of upper lobe bronchi or their branches, for example, are depicted and diagnosed with ease and reliability. And so the values of this method are assessed as follows:

(1) In confirming the existence of obstruction of a bronchus already diagnosed and in demonstrating its probable site of origin; or alternatively in rejecting such a diagnosis, where the bronchi were shown to be normal.

(2) In demonstrating the size and/or depth of a carcinoma already diagnosed, and in revealing the true nature of lesions undiagnosed or inaccurately diagnosed. For radiotherapy purposes localization and indication of extent of lesion, and sometimes of the "treatability" (e.g. by proving mediastinal metastasis not otherwise demonstrable) were of great value.

In this respect the criticism has been raised that an A.P. view taken on the Potter-Bucky table, and "over-penetrated" is quicker to obtain and just as reliable. It is true that such a film may show the lesion, but even if it does (and it frequently fails), it does not localize the lesion in depth or extent.

(3) In demonstrating whether one is dealing with a carcinoma of obstructing or ulcerating type, or whether the lesion is extensive and of the peribronchial infiltrating variety.

(4) In revealing detail, which may enable the radiologist to assess not only whether the case is one of carcinoma of lung, or of mediastinal tumour, but if in the latter group, to suggest the probable nature of the mediastinal invasion. In this connexion it is suggested that where the borders of the tumour can be clearly defined, or where the tumour is seen to push or compress the trachea or bronchi, the tumour is more likely to be a variety of Hodgkin's disease.

(5) Where the invasion occurs without compression or displacement of the air passages, and when its limits are extensive and ill-defined, and particularly if there are comparatively few symptoms, the probability is that one is dealing with a lesion likely to prove very sensitive to irradiation (probably lympho-sarcoma).

(6) Tomography can be exceedingly useful as an aid in determining whether any changes revealed in the chest picture during the follow-up period are due to recurrence of the treated lesion, or whether they are due to mechanical deformities resulting from fibrosis, which, in turn, may result from treatment.

(7) Lastly, it is anticipated that, particularly in the group of obstructing or ulcerating lesions of the bronchus, serial tomography will be of assistance in determining more precisely, both the immediate and the late effects of radiation therapy.

Since the lesions can be seen more clearly by this method, it should be possible, when a sufficient number of proved cases have been reviewed, to decide not only how much the tumour has receded, but possibly also the site at which any recurrence has taken place.

Limitations of tomography.—Tomography does not necessarily indicate the exact nature of the lesion, and even in the case of obstructive lesions, the diagnosis may be indeterminate, as between a simple tumour, carcinoma, or an inflammatory process.

Secondly, although it may, on occasion, be of assistance in deciding how much of the lesion depicted in the routine radiograph is due to malignancy, and how much to infection, the method is frequently unreliable in making this distinction.

Thirdly, very early or very small lesions, whether in lungs, trachea, or main bronchi, are not easy to demonstrate, and may readily be missed. It is in the detection of these small foci that detailed improvements in tomography technique are required.

Lastly, interpretation of tomograms is probably most difficult and least reliable in the assessment of tumours arising in the right main bronchus, and particularly so if bronchiectasis be present in the lower lobe.

CONCLUSIONS

Tomography is not yet used sufficiently widely in the study of the bronchial tree, its value being yet inadequately realized in this country.

The method cannot replace routine radiography; indeed, it can only be really satisfactorily carried out after study of and with measurements obtained from both the P.A. and the lateral view.

Tomography is complementary to bronchoscopic examination, but it is of superior value in the assessment of cases in which bronchoscopic examination has afforded either a negative report or biopsy report of negative value.

The method can, and should, now replace lipiodol bronchography in chest examinations, where the case is likely to be one of carcinoma of the bronchus, and where radiation therapy is indicated. Tomography is easier and quicker; an important advantage in a large clinic, where the case should be diagnosed, assessed, and even treatment planned, before the patient leaves, possibly to return to a far distant home.

Accuracy of diagnosis by tomography demands fine focus tubes, and at the moment a rotating anode tube is an essential feature of any respectable tomographic unit. Increased accuracy of diagnosis is probably related to the distance between the layers or strata selected. A fair degree of accuracy can be obtained by using strata at 1 cm. intervals, but in difficult cases it is probably wise to repeat the examination of the suspected area, using layers at 0.5 cm. apart.

The increasing number of patients presenting themselves with malignant lesions of lung or mediastinum, and the possibility of more effective radiation therapy, afford a wider field for tomography in radio-diagnosis.

Some Observations on Radiology of the Pancreas

By R. A. KEMP HARPER, M.B., D.R.

RADIOLOGY has come to play its important part in the recognition of pancreatic disease as clinical means of diagnosis are still in an elementary stage due to the paucity and indefinite nature of the symptoms. One cannot therefore emphasize too strongly the necessity of looking for evidence of such disease in all obscure cases with upper abdominal symptoms.

All too frequently an examination of the stomach and duodenum ceases when the duodenal cap has been inspected. We must acquire the habit of carrying out careful inspection until the upper coils of jejunum have been adequately visualized, otherwise many pancreatic lesions will remain undisclosed.

Tests of efficiency are still inconclusive in many cases of extensive pancreatic disease, as they are in tests for hepatic function.

SYMPTOMATOLOGY

Acute pancreatitis is usually an urgent surgical emergency and is seldom diagnosed pre-operatively. Pancreatic calculi and calcification are diagnosed mostly as unexpected findings in a film of the upper abdomen and confirmed by the demonstration of their close relationship to the stomach and duodenum after a barium meal study.

Chronic pancreatitis and cyst give rise in the main to vague symptoms, unless the cyst is sufficiently large to be easily palpable clinically. The symptoms are usually those of recurring indigestion of a type not periodic in relation to meals, although exceptionally it may be so. Gaseous distension and upper abdominal tenderness are common features.

Jaundice is an occasional factor in chronic pancreatitis but is a more common finding in carcinoma of the pancreas which may be suggested clinically if there is persistent deep-seated boring pain passing through to the back, a feature of carcinoma of the body or tail infiltrating posteriorly to involve the spine and nerve roots, and coeliac ganglion. There is often also a steady loss of weight as in so many malignant conditions.

Finally, chronic pancreatitis may give rise to changes in small intestinal motility and function as have been frequently reported in the last few years.

RADIOLOGICAL INVESTIGATION

Pneumoperitoneum was persistently advocated by Carelli (*see Case, J. T.*) of Buenos Ayres for some years but he has now modified his views and states that were it not for the frequency of hydatid disease in South America he would find little indication for its use.

Gastric pneumography has been frequently advocated since Engel and Lysholm (1934) introduced this method in 1933, its latest advocate being Thomas (1945) of San Francisco but although in selected cases it may be of assistance as an additional aid, there is no doubt that the routine barium meal with full examination of the duodenum as well as of the stomach, is the most satisfactory method as the mucosa of the duodenum and stomach can be studied in detail to determine the presence or absence of erosion, whilst motility and the finer details of contour cannot be seen by any other means.

The findings of opacities of doubtful nature in the upper abdomen should always be fully studied by postero-anterior and lateral films, and usually also by gastro-duodenal examination to define their relationship to these viscera.

Calcification.—Calcification in the body of the pancreas is occasionally encountered (figs. 1 and 2), and it may also be found as the result of a preceding acute pancreatitis (fig. 3). Calculi have occasionally been reported in the ducts.

The size of the pancreas can be fairly well estimated by the distance between the anterior surface of the spine and the posterior wall of the stomach after gastric visualization either by air or barium; the former is effective in enlargement of the body or tail but the latter is essential for adequate examination of the head. This distance is normally equal to that of the diameter of the body of the vertebra at the same level but in stout subjects it may be considerably greater and in such patients a definite opinion can only be expressed in marked examples.

Cyst formation.—Cystic enlargement is the most easily recognizable of the causes of pancreatic disease in virtue of the smooth-filling defects produced in the parts of the gastro-intestinal tract in close relation to the pancreas. The displacement caused by the cyst varies according to its position and the direction in which the cyst enlarges.

Whilst diagnosis may be easy, it is on occasion extremely difficult and the main conditions to be considered in differential diagnosis are mesenteric and omental cysts, renal cysts and enlargements, retroperitoneal sarcomata, hydatid cysts and hydrops of the gall-bladder, suprarenal tumours and aortic aneurysms.

Cholecystography and urography may also be necessary.

Porta and Roversi illustrate six types of cystic enlargement according to their effect on the surrounding viscera:

(1) Cyst of the head—enlarging and flattening the duodenal loop and causing pressure deformity of the antrum.

(2) Cyst of the body—frequently displacing the stomach upwards.

(3) Cyst of the tail—displacing the greater curve medially and the transverse colon downwards and laterally.

(4) Gastro-hepatic type which displaces the lesser curve downwards and often the third part of duodenum and the transverse colon also (fig. 4).

(5) Gastro-colic type displacing the stomach medially and the transverse colon distally (fig. 5).

(6) Mesocolic type displacing the stomach and transverse colon proximally.

Carcinoma of the pancreas is now being recognized with frequency, largely as a result of the greater awareness of radiologists and of more detailed study of the duodenum as a whole. The head is the commonest site but the body is also frequently affected, a lesion of the tail being much less common. Diagnosis depends on the deformity produced and presence of infiltration of stomach or duodenum. Although carcinoma of the head of the pancreas frequently causes jaundice by obstruction of the common bile duct or ampulla, it is surprising that a fair-sized carcinoma may not involve the ampulla until late in the course of the disease. When the lesion is situated in the region of the ampulla it may produce the appearance described by Frostberg (1938) as a reversed 3 but this occurs in a fairly small proportion of cases of carcinoma of the head of the pancreas and may be present in other types of pancreatic enlargement.

Widening of the duodenal loop and a pressure effect are insufficient evidence on which to diagnose carcinoma although frequently these constitute the only radiological evidence for a long time. The additional factor of erosion or invasion of the duodenal wall or stomach must be found before diagnosing malignancy (fig. 6). A further type is that which produces an annular narrowing of the descending duodenum and which may in certain cases arise from a so-called annular pancreas where the head almost surrounds the duodenum.

Occasionally, enlargement occurs high up in the head of the pancreas and produces a fairly characteristic appearance of the duodenum which is stretched out in the form of a sickle over its superior aspect. Invasion of the antrum of the stomach is also sometimes a feature of carcinoma and difficulty in differentiating from a gastric carcinoma may be considerable unless the enlargement of the head of the pancreas is marked.

The third part of the duodenum may be heavily invaded and it may be impossible to exclude a primary malignant duodenal tumour (fig. 7).

Frequently there is, in addition, abnormal duodenal function with to-and-fro movements, exaggeration of the *plicæ circulares* and retrograde peristalsis or ileus.

Films in both erect and recumbent postures are required and the supine position is generally helpful as the duodenum rings the head most closely in this position. Prone

Accuracy of diagnosis by tomography demands fine focus tubes, and at the moment a rotating anode tube is an essential feature of any respectable tomographic unit. Increased accuracy of diagnosis is probably related to the distance between the layers or strata selected. A fair degree of accuracy can be obtained by using strata at 1 cm. intervals, but in difficult cases it is probably wise to repeat the examination of the suspected area, using layers at 0.5 cm. apart.

The increasing number of patients presenting themselves with malignant lesions of lung or mediastinum, and the possibility of more effective radiation therapy, afford a wider field for tomography in radio-diagnosis.

Arrows indicate enlarged glands within the duodenal loop.

FIGS. 9 and 10.—Enlarged pre-pancreatic glands in Hodgkin's disease causing duodenal compression and antral deformity.

Potter-Bucky films are also most useful and compression films are of great value in demonstrating minor degrees of mucosal destruction.

Lesions of the body and tail require careful examination in every position also and invasion of the stomach wall posteriorly is a helpful finding, together with localized pressure deformity.

Chronic pancreatitis.—Produces enlargement of the gland without duodenal or gastric invasion but adhesions may be present (fig. 8). In general, however, it is impossible to exclude carcinoma as the enlargement may be obvious in the latter condition before duodenal involvement is found.

Jaundice is also sometimes a feature of this condition as well as in carcinoma. Radiological differentiation may thus be as difficult as on those occasions where the hardness of the gland to palpation makes even surgical differentiation impossible.

Whilst being alive to the possibility of intrinsic pancreatic disease, we must not forget that metastases are frequent in the pancreas and other conditions may produce enlargement of the pre-pancreatic glands. This may occur as a mass secondary to a carcinoma of the gastro-intestinal tract, but also in Hodgkin's disease and lymphosarcoma (figs. 9 and 10). Retroperitoneal sarcoma and many other conditions malignant and nonmalignant may also produce glandular enlargement or simulate it.

A tremendous advance in diagnosis will be made when excretory pancreatography is in general use but until a suitable excretory substance is available we must constantly endeavour to raise the standard of accuracy by our present methods, in the diagnosis and differentiation of pancreatic disease. Nor is it probable that examination of stomach and duodenum will even then be dispensed with, as a means of assessing the size of the gland, and its relation to and effect on surrounding viscera will still be required.

Experimental Study of the Vertebral Venous System—Preliminary Report

By A. S. JOHNSTONE, M.B., Ch.B., F.R.C.S., D.M.R.E.

A CLAIM to have found a new route for the spread of metastases is of particular interest to radiologists, and, in presenting this paper, I propose first to summarize the work published by Dr. Batson of Philadelphia (1940) and then record the results of experiments made in an attempt to confirm it.

At the outset I would like to acknowledge the kindness of Dr. Batson in answering my requests for information. His ready response with lucid explanations has left me with a sense of misgiving that somewhere in my experiments a technical error has been committed; but, with the exception of the medium used for injection, the work has been carried out according to his directions.

In 1938 Batson reported a description of the vertebral venous system which he considered to be independent of and quite distinct from the caval, pulmonary and portal systems. It is comprised of complex, interlacing tributaries running along the spinal canal and ramifying in and around the vertebral bodies; it has few valves, very little permanent flow and the pressure is low. The system, in other words, acts as a reservoir of moderately large volume. It is in free communication with the iliac, lumbar, azygos and cranial veins but it is not subject to the same alterations in pressure during coughing or straining. It may thus provide an alternative path for the venous return when the intra-abdominal or intrathoracic pressure is raised.

Batson demonstrated this system in cadavera by the injection of radiopaque material into the deep dorsal vein of the penis. In his earlier attempts he injected a viscid substance—King's yellow—which filled the main caval veins, but, after using vermilion water colour, described as having the consistency of light machine oil, the vertebral system was clearly demonstrated while the caval veins remained empty. The explanation offered for this change of route was that the vertebral veins lay at a lower level than the caval veins—the cadaver lying in the supine position—and the medium of low viscosity freely entered the vertebral system. The greater the quantity injected the further the medium spread up the vertebral column until veins in the skull were filled. The injections were made under fluoroscopic control and stereoscopic radiographs showed the medium to be within the bones.

He extended his experiments to living monkeys and found that on injecting thorotrast into the deep dorsal vein of the penis the inferior vena cava was filled, but, after compressing the abdomen by a tight band, the medium passed into the vertebral system. Batson was forcibly struck by the similarity as shown in the radiographs between the distribution of the opaque venous channels in and around the sacrum, lumbar spine and ilia and the distribution of metastases from cancer of the prostate.

He then discussed the possible methods of spread in these cases. The lymphatic permeation theory of Handley (1922) was dismissed as improbable and the work of Warren on the perineural lymphatic route was scarcely considered. He agreed that metastases were blood-borne but did not favour a spread through the lungs as accepted by many pathologists, notably Willis (1934). He contended that the act of straining would disseminate malignant cells into the vertebral plexus where they would readily settle in or around the adjacent bones and might even pass up into the skull.

To test his hypothesis he injected small mammary veins and found that the opaque medium passed readily into the vertebral system, via intercostal and scapular veins, and thence spread up and down the spine finding its way to the skull, the pelvis and femora. The medium, in addition, entered the upper ends of the humeri and clavicles and the entire distribution corresponded to the spread of breast cancer.

Batson contended further that the free communication of the bronchial veins with this plexus explained the intracranial spread of metastases from bronchial carcinomata and lung abscesses. In a similar way he explained the source of air embolism following pneumothorax.

In our efforts to confirm Batson's findings we have been forced to use different media owing to the scarcity of vermilion water colour, and the bodies used have not previously

FIG. 1.—Vertebral veins filling after ligation of inferior vena cava. Medium used—crude vermilion.

FIG. 2.—Injection of vermilion without ligation. .
Most of the medium lies in the caval system.

FIG. 3.—Medium in vertebral veins as well as caval veins twelve hours after injection.

been preserved for dissection, but have been injected at varying intervals within twenty-four hours of death.

In the first experiments uroselectan and 20% sodium bromide were used and the caval veins were quickly filled. There was very little evidence of opaque medium in the para-vertebral veins so that in subsequent experiments the inferior vena cava, femoral and external iliac veins were ligated. This produced an improved filling of the sacral, ilio-lumbar and ascending lumbar veins, together with many of their small tributaries (fig. 1).

Another series of observations was made using a suspension of crude vermilion, sufficiently dilute to enter minute vessels in the kidney, so that it appeared to be an adequate substitute for vermilion water colour (fig. 2). No attempt was made to estimate the specific gravity of the medium as the vermilion was in suspension.

In some cases the bodies were injected soon after death and radiographs were taken immediately after injection and repeated some twelve hours later. Comparison of these radiographs showed less medium in the caval system and more around the vertebrae in the later films, which suggested that the forces of gravity may have been partly responsible. It was these films which most closely resembled those of Batson (fig. 3).

As a variation some lipiodol was injected into the corpora cavernosa of the penis, and this was followed by xylol to lower the viscosity. Small globules of lipiodol were washed into the venous system and several overlay the vertebral bodies, but it was not possible to localize them within the vertebral system.

One case, in which a moderate filling of the veins around the vertebrae had been obtained, was radiographed after the post-mortem examination. Very little medium remained although the paravertebral veins had not been disturbed.

In all experiments there seemed to be overwhelming evidence that the main return took place through the caval tributaries. On no occasion did the medium reach the skull, the highest point being the entry into the superior hemi-azygos vein after retrograde filling from the azygos vein. The volume of the system seemed to be relatively small. Several attempts were made to demonstrate the communications between the breast and the vertebral system without success. This may have been due to technical faults as the only veins which were sufficiently large to inject led directly to the axillary and subclavicular veins.

DISCUSSION AND SUMMARY

The experiments show that the principal venous drainage from the prostatic plexus flows into the caval system, irrespective of the viscosity of the medium used. Free communication exists with the paravertebral veins and it was felt that the forces of gravity played some part in the experimental filling of these veins. Ligation of the main caval veins did not produce any outstanding increase in the quantity of medium entering the vertebral veins.

It would appear that Batson has tried to establish the existence of a route of metastatic spread principally on the fact that the radiographs of injected pelvic and vertebral veins bear a resemblance to the radiographs of carcinomatous deposits in these bones. If his conclusions are correct it is difficult to explain the relative absence of metastases in the transverse and spinous processes if there is such free communication between the veins.

One has only to see the massive involvement of para-aortic lymph glands in advanced cases of malignant prostate to realize that, although the bone-marrow may have no lymphatics, the perineural lymphatics provide adequate channels for the cells to reach the periosteum and cortical bone, and the work of Warren *et al.* (1936) cannot be so lightly dismissed.

It is also reasonable to conjecture that if the pelvic lymphatics could be injected, the resulting radiograph would produce an appearance corresponding to the distribution of secondary metastases.

In conclusion it is felt that, although some cells may be disseminated along the vertebral venous plexus, there is no definite proof that these vessels provide the main route for the spread of metastases in carcinoma of the prostate, breast and bronchus.

DISCUSSION ON THE USE OF MEDICAMENTS IN DISEASES OF THE COLON AND RECTUM

Dr. F. Murgatroyd: I shall discuss only a few aspects bearing on the treatment of amœbic infection of the bowel, as recent reports increasingly suggest the treatment of this condition to be unsatisfactory.

The drugs commonly used fall into three groups: (1) Ipecacuanha derivatives, of which emetine hydrochloride and emetine bismuth iodide are the most renowned, (2) substituted phenyl arsonates, such as carbarsone and stovarsol, and (3) iodoxyquinoline compounds, of which the chief are chiniofon and diodoquin.

Until recently emetine hydrochloride and emetine bismuth iodide were much less used in the United States of America than in Great Britain, while in the latter country diodoquin was virtually unknown. British practice favours treatment by combinations of the various classes of drugs, a common standard course consisting of emetine bismuth iodide grains 2 or 3 by mouth together with retention enemata of 2½% chiniofon daily for ten days, followed by carbarsone 0.25 grammes by mouth twice daily for a further ten days; sometimes this course is immediately preceded by emetine hydrochloride 1 grain by parenteral injection for a few days. The degree of success obtained by such treatment has been assessed variously as lying between 75 and 95%.

In any endeavour to understand the reason for the failures it is necessary to consider the parasite, the patient and the procedure.

Suggestions have been made that amœbæ may vary in their resistance to the drugs employed, and that inadequate treatment may lead to the development of increased resistance with ultimate failure of the parasite to be influenced by the drugs. There appears little sound experimental evidence to support such a hypothesis in the case of the arsenical and quinoline drugs in amœbiasis, and there are good reasons for doubting the validity of the experiments on which the claims for emetine-resistance rest. In short there seems little justification at present for attributing therapeutic failure in the treatment of amœbiasis to drug-resistance of the amœbæ.

In overt dysentery there are tissue lesions associated with invasion by the amœbæ, and it is widely believed, especially by American workers, that all patients passing *E. histolytica* in their stools, even the asymptomatic carriers, have lesions in the bowel, although these lesions may be only microscopic. However, it is possible that a proportion of the amœbæ may live as commensals, feeding on organic residues or bacteria, in the lumen or on the wall of the gut without actually invading the tissues:

Another series of observations was made using a suspension of crude vermilion, sufficiently dilute to enter minute vessels in the kidney, so that it appeared to be an adequate substitute for vermilion water colour (fig. '2). No attempt was made to estimate the specific gravity of the medium as the vermilion was in suspension.

In some cases the bodies were injected soon after death and radiographs were taken immediately after injection and repeated some twelve hours later. Comparison of these radiographs showed less medium in the caval system and more around the vertebræ in the later films, which suggested that the forces of gravity may have been partly responsible. It was these films which most closely resembled those of Batson (fig. 3).

As a variation some lipiodol was injected into the corpora cavernosa of the penis, and this was followed by xylol to lower the viscosity. Small globules of lipiodol were washed into the venous system and several overlay the vertebral bodies, but it was not possible to localize them within the vertebral system.

One case, in which a moderate filling of the veins around the vertebræ had been obtained, was radiographed after the post-mortem examination. Very little medium remained although the paravertebral veins had not been disturbed.

In all experiments there seemed to be overwhelming evidence that the main return took place through the caval tributaries. On no occasion did the medium reach the skull, the highest point being the entry into the superior hemi-azygos vein after retrograde filling from the azygos vein. The volume of the system seemed to be relatively small. Several attempts were made to demonstrate the communications between the breast and the vertebral system without success. This may have been due to technical faults as the only veins which were sufficiently large to inject led directly to the axillary and subclavicular veins.

DISCUSSION AND SUMMARY

The experiments show that the principal venous drainage from the prostatic plexus flows into the caval system, irrespective of the viscosity of the medium used. Free communication exists with the paravertebral veins and it was felt that the forces of gravity played some part in the experimental filling of these veins. Ligation of the main caval veins did not produce any outstanding increase in the quantity of medium entering the vertebral veins.

It would appear that Batson has tried to establish the existence of a route of metastatic spread principally on the fact that the radiographs of injected pelvic and vertebral veins bear a resemblance to the radiographs of carcinomatous deposits in these bones. If his conclusions are correct it is difficult to explain the relative absence of metastases in the transverse and spinous processes if there is such free communication between the veins.

One has only to see the massive involvement of para-aortic lymph glands in advanced cases of malignant prostate to realize that, although the bone-marrow may have no lymphatics, the perineural lymphatics provide adequate channels for the cells to reach the periosteum and cortical bone, and the work of Warren *et al.* (1936) cannot be so lightly dismissed.

It is also reasonable to conjecture that if the pelvic lymphatics could be injected, the resulting radiograph would produce an appearance corresponding to the distribution of secondary metastases.

In conclusion it is felt that, although some cells may be disseminated along the vertebral venous plexus, there is no definite proof that these vessels provide the main route for the spread of metastases in carcinoma of the prostate, breast and bronchus.

Lt.-Col. W. H. Hargreaves: At the Queen Alexandra Military Hospital at Shenley during the past two years, 699 patients with amœbiasis in various stages have passed through our hands.

In 1944, about one-fifth of our patients with chronic amœbic dysentery were bed-ridden with foul diarrhœa, their stools containing blood, mucus, and amœbæ. They complained of almost persistent colicky pain, and their colons were palpable and tender. Sigmoidoscopy as a rule showed extensive ulceration, the mucosa between the ulcers being swollen and injected.

These patients presented a desperate problem. Some had been under treatment for as long as 2 years, dating from the fall of Burma in 1942, when chaos reigned; it was often several weeks before they got back to India, where hospitals were overflowing and drugs scarce. By the time they reached us they had been given repeated courses of anti-amœbic drugs, often at home as well as abroad, including emetine injections sometimes running into three figures, and they had been labelled emetine-resistant. Many of them had also been given courses of sulphaguanidine or succinylsulphathiazole (sulphasuxidine). In May 1944 one of these patients died. Acting on the assumption that secondary bacterial infection was preventing a response to anti-amœbic drugs, we then tried penicillin at the suggestion of General Biggam as a last resort for an apparently moribund patient. He responded dramatically, and although the amœbic infection persisted, his symptoms subsided and on sigmoidoscopy the ulceration was seen to heal. After two courses of penicillin, standard anti-amœbic treatment was given; when finally reviewed four months later, he was still well.

The outlook of these distressing cases was changed considerably as the result of this experiment. Penicillin has not been found to have any significant effect on *Entamoeba histolytica*, but we have found repeatedly that it renders severe refractory cases of chronic amœbic dysentery more amenable to drugs with a specific action on the amœbæ. The symptomatic relief is very striking. Patients transferred to us on the dangerously ill list needing morphia to relieve their pain have become free from colic after two or three days on penicillin and have begun to pass formed stools. Repeatedly on sigmoidoscopy during the course of penicillin treatment we have seen improvement, the swelling and injection of the mucosa subsiding so that ulcers become more superficial in appearance and begin to epithelialize.

We now give a course of penicillin which lasts just over eight days, totalling 2 million units, in three-hourly doses of 30,000 units intramuscularly. To combat some of the organisms which are not sensitive to penicillin we also give sulphasuxidine at the same time by mouth—20 grammes daily. Occasionally it has been necessary to repeat the course—for instance, in one case where numerous small abscesses could be seen bursting through the mucosa when the sigmoidoscope was introduced.

The anti-amœbic treatment which we give to chronic cases now usually consists of a 12-day course of emetine bismuth iodide—3 grains of the loose powder in 1 gramme gelatin capsules at night—combined with daily retention enemata of chiniofon, followed by a course of diodoquin—three tablets thrice daily by mouth for twenty days. Tests of cure are carried out one month after the end of this treatment. Three of the first 50 cases relapsed after this period. One of these had refused to have any more EBI after his penicillin course. We had no comparable series of patients treated with anti-amœbic drugs only, as the cases described were very severe and had previously been given repeated courses of routine treatment without success.

This success with penicillin in chronic amœbic dysentery naturally led us on to try it in chronic ulcerative colitis. Claims for any treatment in this disease must be made very timorously owing to its notorious tendency to remit spontaneously. As luck would have it, however, our first patient appeared to respond well. This was a woman aged 30 who had been ill for eighteen months, during which she had been treated with medicated enemata and sulphaguanidine. She was critically ill and sigmoidoscopy showed severe ulceration. Two weeks after the end of a course of penicillin and sulphasuxidine, her symptoms had subsided and sigmoidoscopy was normal. This was in October 1944, and since then she has remained well apart from periodic constipation, and in fact she has married. When I saw her last month, sixteen months after the treatment, she was free from symptoms and her bowel was normal on sigmoidoscopy.

Our second patient had regional colitis and had been treated previously with sulphaguanidine and sulphasuxidine without success. He was symptom-free and normal on sigmoidoscopy following two courses of penicillin and sulphasuxidine separated by an

such parasites might presumably be little influenced by amœbicidal drugs present in the blood and tissues, in which case successful therapy might depend upon having an adequate concentration of drug in the contents of the bowel. Unfortunately to this question of precise pathology a certain answer cannot be given.

There are also vexatious uncertainties regarding the exact state and distribution of the drugs themselves in the body. For example, emetine, which *in vitro* has such a potent direct action upon *E. histolytica*, fails when injected parenterally, to cure intestinal infections with this parasite in cats. In these animals the drug appears largely to be eliminated in the urine, and it may be that this mechanism prevents the tissue-concentration of the drug from rising to, or being maintained sufficiently long at, an amœbicidal level. Alternatively, these animals may metabolize or render impotent the drug in some manner different from that obtaining in man. Even in man, however, there is abundant evidence to show that daily injections of emetine hydrochloride 1 grain fail to cure a large proportion of intestinal infections, some placing the relapse rate as high as 90%, and with chronic carriers the results are particularly poor. It may be that comparatively small differences in the metabolism or elimination of the drug between individual patients may become manifest clinically by the gross difference between cure and relapse. Save in a small percentage of patients, emetine hydrochloride 1 grain daily appears either insufficient to maintain in the tissues an amœbicidal milieu for a sufficient length of time to eradicate the infection or it fails to destroy the parasites in the lumen of the gut, and so relapse occurs. Yet this method of treatment appears to be considered adequate, especially in India.

On the other hand, Dobell found almost thirty years ago that emetine bismuth iodide 3 grains daily by mouth for 12 days cured about 90% of carriers of *E. histolytica*. From this it would appear that a comparable amount of emetine given by mouth may, possibly owing to slower absorption, maintain an amœbicidal concentration of drug in the tissues or gut for a more prolonged period, and so sterilize the infection. It may not be without significance in this connexion to note that when emetine is given by mouth only on alternate days, as auremetine in the course employed at Liverpool for many years, a relapse rate as high as 90% has recently been recorded for chronic infections so treated.

The necessity for giving emetine bismuth iodide in a suitable form so that it becomes liberated and dispersed, and possibly absorbed, seems generally agreed, even if often neglected in actual practice. It may also be necessary to maintain the dosage at 3 grains daily, and the suggestion of recent years that 2 grains is sufficient may not be without danger. The addition of emetine hydrochloride parenterally in "loading" doses at the beginning of treatment with emetine bismuth iodide seems reasonable, but I am not convinced that the addition of chiniofon, carbarsone or similar drugs materially improves the ultimate result, although, in the present state of our ignorance and since there is no evidence of any "interference phenomenon" when such drugs are used together, it would seem justifiable to retain their association.

Some years ago attention was drawn to the possible part played by concomitant bacteria in the survival and invasiveness of the amœba; and more recently Colonel Hargreaves, being impressed by the secondary infection of the bowel of a fatal case, tried the effect of associating penicillin and succinylsulphathiazole with the specifically amœbicidal drugs. He observed that œdema and hyperemia of the mucous membrane subsided and that the ulcers became more superficial when treated with the penicillin and the sulphonamide compound; and he stated that "there seems little doubt that in this way the amœbæ are rendered more easy of access to emetine." Whether this be true or not, it would appear that his view is that emetine remains the ultimate amœbicidal agent, and it is difficult therefore to believe that penicillin and sulphonamide can make much difference statistically to the total results of treating amœbiasis, since in general the cases refractory to treatment are not necessarily those with gross lesions. In fact most authors stress the greater difficulty of sterilizing the chronic cyst carriers, in whom lesions if present at all are often minimal. It would therefore be of great interest to know whether the combined treatment does in fact confer any benefit in the treatment of the less acute and less severe cases. While there seems no doubt of its value in gravely advanced and secondarily infected cases, the primary aim should be to eradicate the infection before the patient reaches such a state. To this end the great practical need is a wider appreciation and application of what is already known about the treatment of amœbiasis, while fundamentally further insight is desirable into the mechanism of action in man of those drugs which, properly used, still justify the promise they revealed more than a quarter of a century ago.

Lt-Col. W. H. Hargreaves: At the Queen Alexandra Military Hospital at Shenley during the past two years, 699 patients with amœbiasis in various stages have passed through our hands.

In 1944, about one-fifth of our patients with chronic amœbic dysentery were bed-ridden with foul diarrhœa, their stools containing blood, mucus, and amœbæ. They complained of almost persistent colicky pain, and their colons were palpable and tender. For example, emetine, which *in vitro* has such a potent direct action upon *E. histolytica*, fails when injected parenterally, to cure intestinal infections with this parasite in cats. In these animals the drug appears largely to be eliminated in the urine, and it may be that this mechanism prevents the tissue-concentration of the drug from rising to, or being maintained sufficiently long at, an amœbicidal level. Alternatively, these animals may metabolize or render impotent the drug in some manner different from that obtaining in man. Even in man, however, there is abundant evidence to show that daily injections of emetine hydrochloride 1 grain fail to cure a large proportion of intestinal infections, some placing the relapse rate as high as 90%, and with chronic carriers the results are particularly poor. It may be that comparatively small differences in the metabolism or elimination of the drug between individual patients may become manifest clinically by the gross difference between cure and relapse. Save in a small percentage of patients, emetine hydrochloride 1 grain daily appears either insufficient to maintain in the tissues an amœbicidal milieu for a sufficient length of time to eradicate the infection or it fails to destroy the parasites in the lumen of the gut, and so relapse occurs. Yet this method of treatment appears to be considered adequate, especially in India.

On the other hand, Dobell found almost thirty years ago that emetine bismuth iodide 3 grains daily by mouth for 12 days cured about 90% of carriers of *E. histolytica*. From this it would appear that a comparable amount of emetine given by mouth may, possibly owing to slower absorption, maintain an amœbicidal concentration of drug in the tissues or gut for a more prolonged period, and so sterilize the infection. It may not be without significance in this connexion to note that when emetine is given by mouth only on alternate days, as auremetine in the course employed at Liverpool for many years, a relapse rate as high as 90% has recently been recorded for chronic infections so treated.

The necessity for giving emetine bismuth iodide in a suitable form so that it becomes liberated and dispersed, and possibly absorbed, seems generally agreed, even if often neglected in actual practice. It may also be necessary to maintain the dosage at 3 grains daily, and the suggestion of recent years that 2 grains is sufficient may not be without danger. The addition of emetine hydrochloride parenterally in "loading" doses at the beginning of treatment with emetine bismuth iodide seems reasonable, but I am not convinced that the addition of chiniofon, carbarsone or similar drugs materially improves the ultimate result, although, in the present state of our ignorance and since there is no evidence of any "interference phenomenon" when such drugs are used together, it would seem justifiable to retain their association.

Some years ago attention was drawn to the possible part played by concomitant bacteria in the survival and invasiveness of the amœba; and more recently Colonel Hargreaves, being impressed by the secondary infection of the bowel of a fatal case, tried the effect of associating penicillin and succinylsulphathiazole with the specifically amœbicidal drugs. He observed that œdema and hyperæmia of the mucous membrane subsided and that the ulcers became more superficial when treated with the penicillin and the sulphonamide compound; and he stated that "there seems little doubt that in this way the amœbæ are rendered more easy of access to emetine." Whether this be true or not, it would appear that his view is that emetine remains the ultimate amœbicidal agent, and it is difficult therefore to believe that penicillin and sulphonamide can make much difference statistically to the total results of treating amœbiasis, since in general the cases refractory to treatment are not necessarily those with gross lesions. In fact most authors stress the greater difficulty of sterilizing the chronic cyst carriers, in whom lesions if present at all are often minimal. It would therefore be of great interest to know whether the combined treatment does in fact confer any benefit in the treatment of the less acute and less severe cases. While there seems no doubt of its value in gravely advanced and secondarily infected cases, the primary aim should be to eradicate the infection before the patient reaches such a state. To this end the great practical need is a wider appreciation and application of what is already known about the treatment of amœbiasis, while fundamentally further insight is desirable into the mechanism of action in man of those drugs which, properly used, still justify the promise they revealed more than a quarter of a century ago.

tive amœbæ in the stools, and is given intramuscularly, 1 grain daily for four to eight days. When symptomless amœbic ulceration or cysts are chance findings no intramuscular emetine is required. EBI and chiniofon are then started at once.

With emetine injections a fall in blood-pressure occurred only if given for longer than eight days. Blood-pressure records were, therefore, regarded as unimportant with standard dosage. All our subjects, however, were European or American troops; reactions may admittedly be commoner in Indians whose physique is slighter.

The injections are followed without a break by the course of EBI, twelve consecutive daily doses of 3 grains by mouth, together with retention enemata of chiniofon. EBI is normally dispensed in gelatin or sugar-coated capsules both of which render disintegration and absorption uncertain. We gave it direct as powders either in a spoonful of jam or on the back of the tongue with a drink. EBI is customarily administered at night with a barbiturate sedative to allay the nauseating effect, but we found it was well tolerated and toxic effects need not be anticipated. The stools should always be inspected as a control of assimilation; they are dark from the bismuth in the compound.

Chiniofon enemata, consisting of 7 oz. of 2½% solution daily for these twelve days, were given simultaneously with EBI. (Synonyms: yatren, quinoxyl, quinosulphan.) To help to retain each enema for at least six hours the foot of the bed is raised on 8 in. blocks. The patient should lie in turn, for half an hour each on his left side, back and right side. This drill keeps him recumbent but has no other particular value, for we have shown by X-rays that enemata reach the cæcum from the supine position. Patients will often tolerate with benefit a gradual increase both in volume and strength of the enemata. Towards the end of the EBI course some diarrhœa is common and upsets retention unless an alkaline bowel washout is given before. In a busy ward the sterilization of apparatus must be supervised to prevent cross infection of bacillary exudate.

Finally, for a further twelve days, carbarsone (or stovarsol) was given, 4-grain tablets twice daily, to eradicate cysts, and the patient was then allowed up.

We had a small experience of Kurchi bismuth iodide at a time when EBI was scarce but were not convinced that it replaced EBI as an active amœbicide.

Emetine resistance.—One has learnt that interruption of treatment is a cogent cause of chronicity and relapse. Its relative incidence is high, for example, among doctors, because we are sometimes too impatient to undergo the prescribed full course and are inclined to modify it to our convenience. In one's earlier experience, when treatment was not standardized and soldiers were denied the proper drugs through short supply, relapses were common and many apparently intractable cases were invalidated home. We now realize that few of these so-called emetine-fast cases had a completed course of treatment controlled in hospital. Latterly it became rare, except for operational reasons, to evacuate any patient with chronic amœbiasis. Emetine resistance clearly is more apparent than real. There are perhaps exceptional cases which do not at first respond to standard treatment, yet even these will generally react to a second course repeated after an interval, when penicillin and sulphasuxidine may be needed to clear secondary colonic infection.,

CONCLUSIONS

The continuous sequence of treatment is all-important. Hypodermic emetine deals only with initial symptoms; by itself it does not cure. EBI (by mouth) and chiniofon (enemata) are possibly the keystones of treatment. Carbarsone should clear residual cysts. The twelve-day periods in therapy are arbitrary; they may be prolonged but never reduced. Bed-rest is essential for the first two to three weeks but diet restriction and purges are not. Convalescence for three weeks is desirable, followed by readmission to hospital for six daily stool tests of cure and final sigmoidoscopy.

Mr. T. Howard Somervell: South Indian experiences in colonic disease.—*Amœbic dysentery:* Most of our work in the medical wards seems to be clearing up the failures of other doctors by giving continuous courses of emetine to patients who have already had scores of injections, but never more than five or six at one time.

Amœbæ often disappear from the stools, so do blood and the characteristic degenerated leucocytes, after six emetine injections. The patient feels that he has "had enough," and the doctor, always willing to please, lets him off for a few days before giving more emetine. The patient recovers his composure, so do the amœbæ. They have had a kind

interval of two weeks during which daily retention enemata of sulphasuxidine were given. He relapsed after seven months, but has responded again to another course of treatment.

We have treated 7 other patients with ulcerative colitis and proctitis. All showed a satisfactory response, but 2 had persistent granularity in the lower part of the rectum—one after four courses of treatment. Only one patient had a ribbon-like colon radiologically, and there was no change in this appearance after treatment, although ulceration had healed. These patients were definitely improved, but one cannot claim that they were cured.

Our clinical experiences are open to the criticism that they did not always have strict bacteriological control. Occasionally we have been able to isolate penicillin-sensitive streptococci and staphylococci from the dysenteric cases, and in 2 cases of ulcerative colitis penicillin-sensitive staphylococci have been found.

My conclusion is that penicillin is well worth a more extensive trial in chronic ulcerative colitis.

I mentioned our first case of ulcerative colitis in November 1944 at a meeting of the Royal Society of Tropical Medicine and Hygiene. After this meeting, Sir Alexander Fleming was asked to give penicillin to another patient who was being despaired of after seven months' illness. He did so, after isolating penicillin-sensitive staphylococci. The patient recovered, and has remained well now for over a year.

Dr. J. L. Lovibond: I propose to review a clinical impression of approximately 1,000 hospital cases of amœbic dysentery seen in Ceylon, Assam and Burma between 1942 and 1945.

Diagnosis.—From a study of tropical disease in the tropics one learns that its behaviour may differ much from the classical teaching. Although chronic amœbiasis was an important cause of insidious ill-health in South East Asia Command, cases were rarely labelled "chronic amœbic dysentery" as a first diagnosis because the symptoms are generally more negative than positive. Diagnosis from the history alone is difficult since dysentery *per se* is not a regular feature of chronic amœbiasis and, even at the onset, can be mild and pass unnoticed. Indeed, in an endemic area, while an individual is becoming acclimatized, short bouts of diarrhoea are usual.

Symptoms may simulate various disorders, ranging from appendicitis to exhaustion neurosis, but unexplained loss of weight in a subject home from the East is always suggestive.

Not uncommonly a latent chronic amœbic infection was brought to light by the activation of an intercurrent acute illness, for example malaria or bacillary dysentery or even after a major surgical operation.

Loss of weight, fatigue, irritability or anxiety symptoms in men with a negative sigmoidoscopy but with cysts in their stools, responding to anti-amœbic treatment, suggest that constitutional symptoms, with or without clinical hepatitis, may predominate when the seat of infection is chiefly cæcal, though when the rectum is involved dysentery and pain are manifest.

All dysenteric patients were sigmoidoscoped on admission to hospital and again before discharge. Our only preparation was for the patient to defæcate before examination. This simple routine was of great diagnostic value, especially in the apparently cured. Thus, many cases of acute bacillary dysentery after sulphaguanidine were found to harbour unsuspected chronic amœbic ulceration in the rectum. Although this drug successfully eliminated an acute bacillary infection from the bowel it made the microscopic detection of entamœbæ more difficult afterwards. We felt that sulphaguanidine had, maybe, some specific anti-amœbic action, enough to rid the bowel contents of amœbæ and cysts yet not enough to heal, for vegetative forms remained in the ulcers.

Treatment.—Treatment is begun at once after diagnosis and the detailed routine of a full consecutive course must be followed. Although various doses and combinations of drugs have been advocated in the past, treatment now is standardized. All patients, irrespective of the stage of their disease, are put to bed and given a course of emetine bismuth iodide by mouth, chiniofon by bowel and carbarsone. Emetine hydrochloride is reserved solely for patients with symptoms, intestinal or constitutional, or with vegeta-

tive amœbæ in the stools, and is given intramuscularly, 1 grain daily for four to eight days. When symptomless amœbic ulceration or cysts are chance findings no intramuscular emetine is required. EBI and chiniofon are then started at once.

With emetine injections a fall in blood-pressure occurred only if given for longer than eight days. Blood-pressure records were, therefore, regarded as unimportant with standard dosage. All our subjects, however, were European or American troops; reactions may admittedly be commoner in Indians whose physique is slighter.

The injections are followed without a break by the course of EBI, twelve consecutive daily doses of 3 grains by mouth, together with retention enemata of chiniofon. EBI is normally dispensed in gelatin or sugar-coated capsules both of which render disintegration and absorption uncertain. We gave it direct as powders either in a spoonful of jam or on the back of the tongue with a drink. EBI is customarily administered at night with a harbiturate sedative to allay the nauseating effect, but we found it was well tolerated and toxic effects need not be anticipated. The stools should always be inspected as a control of assimilation; they are dark from the bismuth in the compound.

Chiniofon enemata, consisting of 7 oz. of 2½% solution daily for these twelve days, were given simultaneously with EBI. (Synonyms: yatren, quinoxyl, quiniolulpham.) To help to retain each enema for at least six hours the foot of the bed is raised on 8 in. blocks. The patient should lie in turn, for half an hour each on his left side, back and right side. This drill keeps him recumbent but has no other particular value, for we have shown by X-rays that enemata reach the cæcum from the supine position. Patients will often tolerate with benefit a gradual increase both in volume and strength of the enemata. Towards the end of the EBI course some diarrhœa is common and upsets retention unless an alkaline bowel washout is given before. Convalescence for three weeks is desirable, followed by readmission to hospital for six daily stool tests of cure and final sigmoidoscopy.

Mr. T. Howard Somervell: *South Indian experiences in colonic disease.*—*Amœbic dysentery:* Most of our work in the medical wards seems to be clearing up the failures of other doctors by giving continuous courses of emetine to patients who have already had scores of injections, but never more than five or six at one time.

Amœbæ often disappear from the stools, so do blood and the characteristic degenerated leucocytes, after six emetine injections. The patient feels that he has "had enough," and the doctor, always willing to please, lets him off for a few days before giving more emetine. The patient recovers his composure, so do the amœbæ. They have had a kind

of anæsthetic, from which they recover, to be narcotized once more by another few injections of emetine—but not killed.

In our experience emetine, or EBI, must always be given *every* day for at least ten days, better for twelve days. In early, acute cases this is usually enough to rid the body of the amœbæ, but a few days (without interval) of carbarsone t.d.s. makes matters more certain.

The stressing of the importance of continued daily treatment is very important in India, where so many doctors seem to be completely ignorant of its significance.

The chronic cases with cysts require adjuvant treatment with quinoxyl retention enemata. Our practice was to give these on the 2nd, 3rd, 9th, 10th, and 11th days of the emetine or EBI administration.

During the latter part of the war we could not obtain quinoxyl, and we substituted carbarsone, 4 times daily for 5 days, beginning it on the 8th day of emetine injections, or enterovioform enemata daily for ten days.

In the last two years we have dealt with 130 cases of this kind, many of whom have had previous inadequate emetine treatment, and many others suffering from much malnutrition through famine.

Average number of days in hospital fifteen, deaths six. The remainder went home clinically cured and free from amœbæ to pathological examination. There were 4 cases of arsenical dermatitis.

No case was considered "cured" until negative to five successive examinations of feces, and latterly to sigmoidoscopy also. Presence of degenerated leucocytes is treated as positive, even though amœbæ are not seen.

The rectum in amœbiasis.—During the last few years we have seen 10 cases of amœbic disease of the rectum. 5 of these were proctitis with fistule, the fistule being very deep, opening into the rectum about 3 in. from the anus. Emetine, as always most effective in extra-colonic amœbic disease, clears up the amœbic infection, but colostomy also is always required. 2 cases refused colostomy and never healed. 3 cases had colostomy and plastic rectal operations, and were healed; one of these afterwards broke down three years after the closure of the colostomy. 5 cases had fibrosis of the rectum. In these 5, the mucous membrane was teeming with active amœbæ. After a full course of emetine, very gradual dilatation was tried, and was effective in 3 cases. Permanent colostomy was necessary in the other 2 cases, in which the rectum for 3 or 4 in. would scarcely admit a pencil, nor could it be safely dilated.

We have also had 4 cases of burrowing abscesses of the perineum and buttock, in which amœbæ were present. These had long histories of ineffective treatment. They all cleared up with emetine and excision of the walls of the abscesses in a surprisingly short time.

(Major R. M. S. McConaghey reviewed 19 similar cases, nearly all in China, and only one from India. See *Indian med. Gaz.*, 1945, 80, 79.)

It is my opinion that all cases of carcinoma of rectum in the tropics should be tested for amœbæ before operation and/or radium treatment is embarked upon.

Bacillary and Amœbic Dysentery Together.

Speaking as a patient who suffered during the 1914-18 war with a combination of both diseases, one (amœbic) of which was only discovered on my demobilization in 1920, I am convinced that there are many cases who have both infections, and in whom the acute stage of one infection has lit up the other.

Colonel J. R. Davidson tells me that in the recent war it became the custom to treat all dysentery cases with sulphaguanidine in the line, and only evacuate them if there was no adequate effect in twenty-four to forty-eight hours.

If these cases proved at the base to have amœbæ, the routine then was (for all cases, acute and chronic):—

Emetine 1 grain daily for 6 days	} 12 days— {	Yatren 5th—12th day
EBI 3 grains daily for 6 days		8 oz. 2½% rel. enema
		Days 13—14 Yatren enema only
		Days 15—24 Carbarsone 0.25 grammes twice daily

Only 3% of chronic cases relapsed after this treatment, and no acute cases. This for acute cases is extremely thorough treatment, and is what I consider a full course for

a chronic case. If you have the drugs, and the patients under your control, it is certainly ideal as far as thoroughness is concerned. The routine exhibition of a sulpha drug for the first two days of all dysenteries is probably to be recommended. It can do nothing but good even in a purely amoebic case.

Bacillary dysentery.—In fresh cases of bacillary dysentery, of not more than three days duration, the sulphonamide drugs are, as we all know, brilliantly successful. But so are several other treatments.

In more chronic cases, however, the situation is far more serious. Hitherto the problem of chronic bacillary dysentery has been a serious one; but to the surprise of many people it has been found that sulphamezathine and sulphaguanidine, and even sulphapyridine, produce remarkably good results with a high percentage of cures in chronic cases.

In 1945 we treated 85 cases of bacillary dysentery, and many of these were very weak on admission, some of them having a choleraic type of dysentery. Most were infected with Flexner bacilli, and many were suffering from a degree of starvation owing to war conditions. The standard treatment was:

Sulphapyridine or sulphamezathine, 3 grammes, then 1 gramme four-hourly for two days, followed by
Sulphaguanidine, 1 gramme four-hourly for two days.
(Sulphaguanidine, 3 grammes four-hourly, the usual dose, caused toxic symptoms in many cases.)

In this series there were 8 deaths, nearly 10%, a far better result than we have had in a similar series of emaciated cases with any other treatment. Strangely enough we have found sulphapyridine more effective, and apparently less toxic, than sulphaguanidine for bacillary dysentery.

With regard to the complications of bacillary dysentery, the one which is made little of in most textbooks, but is very common in S. India, is chronic peritonitis with massive serous effusion. This is very resistant to treatment, and if the patients are aspirated they soon fill up again. It is said that omentopexy has been followed by very bad results.

Tuberculous disease of the colon, etc.—In South India we have had a large number of cases of hyperplastic disease of the colon due to the tubercle bacillus, also 8 cases of Crohn's regional "ileitis" in the colon.

For these conditions we have found no drug to be of the slightest use. We have never used sulphasuxidine, however. (Amoebic and other infections are, of course, excluded by full pathological investigations).

The treatment must be surgical, and ileocolic anastomosis as well as excision of the tuberculous colon must be done at one sitting. If ileotransverse anastomosis is done and the tuberculous colon (usually caecum) is left, the patient's health may improve, but the colon nearly always gets worse, and eventually requires a more extensive operation for its removal.

In 51 cases, there were 4 deaths, no deaths in the last 30 cases, perhaps owing to the sewing of the anastomosis in 3 layers.

If the appearance at operation is quite certainly that of Crohn's disease, anastomosis alone may be done; the disease progresses much more slowly than tuberculous trouble, and does not tend to get adherent, to form abscesses, etc.

Diagnosis between the two is helped by the sedimentation test. Average figures for TB, 0 ... 56 ... 70. Average figures, Crohn, 0 ... 26 ... 38.

Mr. C. Naunton Morgan: It is probable as an aftermath of world-wide war, that both bacillary dysentery and certainly amoebiasis occurring in the United Kingdom will give rise to difficulties and misdiagnosis unless the protean nature of the latter disease, and especially the fact that amoebiasis may remain latent without symptoms for many years, are borne in mind.

Emetine has proved of great value in both the diagnosis and treatment of amoebiasis, as this disease presents itself to the surgeon.

Amoebic granulomata (amoeboma) occurring in the colon and rectum in the Eastern theatres of war sometimes made the differential diagnosis of these tumours from carcinoma

difficult, especially since both malignant disease and amœbiasis may coexist. In M.E.F., of 21 patients with malignant lesions of the colon and rectum referred to the rectal centre, no fewer than 12 were diagnosed as bacillary or amœbic dysentery, and in 5 of these cases the carcinoma had been at first mistaken for an amœboma. In 7 cases bacillary or amœbic dysentery were found associated with a carcinoma.

Apart from biopsy, which may be fatally misleading unless a representative piece is removed for section, emetine is of great value in differential diagnosis. In the large majority of cases an amœboma melts away in a dramatic manner following the administration of a course of emetine injections and the diagnosis is established even though the amœba, which may be lurking in the depths of the tumour, cannot be isolated. However, on very rare occasions when destruction of the bowel wall has progressed beyond the stage at which anatomical recovery is possible, surgical intervention becomes necessary, not only to restore the patient to health, but more often because malignant disease cannot be excluded with certainty. A tumour of the cæcum with proven amœbiasis was excised because, though the mass diminished in size after several courses of emetine, etc., it still remained. At operation and on macroscopic examination the cæcal tumour was thought to be an amœboma, but section showed it to be a carcinoma.

The dangers of abdominal and rectal operations in the presence of amœbiasis or bacillary infection are now generally recognized so that in suspected cases, when there is no indication for urgent operation, specific therapy must be given before surgical intervention.

Amœbic typhlitis and acute appendicitis caused anxiety in the diagnosis of the acute abdomen. However, when acute appendicitis is diagnosed early, and especially when there are signs and symptoms indicating rapid extension of intraperitoneal infection or obstruction to the appendix lumen, even though amœbic infection is present, immediate operation must be performed. If typhlitis is found at operation, even though amœbic infection is not proven, but probable, it is wise to commence specific therapy at once.

Invasion of the skin at the site of the operation wound may be the first indication of the presence of amœbiasis. The skin lesions also respond rapidly to emetine.

It is worthy of record that an amœbic ulcer of the anal canal skin, an amœbic fissure-in-ano, has been observed getting larger during the administration of carbarsone, and fading away soon after emetine was exhibited.

Both bacillary and amœbic infection may be present at the same time, and on sigmoidoscopy the diffuse inflammation of the mucosa in the former may overshadow the tiny lesions of amœbiasis. In such cases, repeated sigmoidoscopy after the administration of sulphaguanidine for about a week will reveal the two-edged nature of the infection.

Though the sigmoidoscopic appearances of amœbic and bacillary dysentery are described as being clear cut, this is not the case, and tiny localized ulcers may occur in otherwise normal mucous membrane, due to Flexner infection; whilst on the other hand, diffuse granular proctitis may be amœbic in origin. The administration of emetine and/or sulphaguanidine may be the only method of establishing a diagnosis.

Succinylsulphathiazole in the Surgery of the Rectum and Colon.

Succinylsulphathiazole (sulphasuxidine) introduced by Poth in 1942, reduces the bacterial count of the intestinal contents and also makes the faeces less bulky and of a slightly sticky consistency, so allowing their removal from the lumen with less likelihood of contamination. In addition, the drug appears to have a slightly laxative effect. Increase of bleeding from a carcinoma has been observed by Firor and others, after five days' administration of the drug.

Though the dosage recommended in terms of body-weight, usually 8 to 10 grammes daily, was used in 1942 in M.E.F., investigation of our cases by Mackenzie at the 15th Scottish General Hospital showed that the breakdown of this drug is unlikely to exceed 5%, and we came to the conclusion that 20 grammes daily for four days, followed by 20 grammes in one dose on the day of the operation was the most efficient dosage. Results with 5 grammes, 10 grammes and 20 grammes dosage were compared. It was found that culture of a scraping of the carcinomatous ulcer grew no *B. coli* when a 20-grammes dose was used for five days, and that in the case of ileostomy for complete colectomy and excision of the rectum, *B. coli* in the small gut had been laid low by succinylsulphathiazole.

When a preliminary colostomy has been performed, succinylsulphathiazole 20 grammes in 6 oz. of half strength mucilage is inserted into the excluded bowel daily for ten to fourteen days following lavage.

Sulphasuxidine was used before operation in 33 cases, and in only 1 was there evidence of intraperitoneal infection. An abdominal abscess developed insidiously and without fever, following a combined excision of the rectum, bursting into the general peritoneal cavity on the eleventh day. This patient quickly recovered after drainage of the abdominal cavity. Apart from this one complication, the smooth convalescence following operation was striking.

Sulphonamides which control the intestinal flora are important adjuvants in the surgery of the large bowel, but though the number of organisms in the intestine may be controlled, these drugs do not allow any relaxation in the care and established principles of the surgery of the colon and rectum.

Mr. A. Dickson Wright: With the discovery of sulphonamides and their amazing properties the long-dreamt-of possibility of sterilizing the colonic contents became a practical possibility. The difficulty was that the sulphonamides were absorbed in the small intestine and if they were wanted for colon sterilization introduction by enema was necessary. This was tried and had some success, but it was an uncertain method of administration; it was necessary to have a compound which would not be absorbed when taken by mouth and so would be thoroughly mixed with the faeces and exercise a uniform sterilizing action on the contents. This was not difficult to achieve with all the chemical linkages available and neoprontosil, sulphaguanidine, sulphasuxidine and sulphathalidine were all evolved in turn, each with a diminishing absorbability but unimpaired bactericidal action.

Having achieved the sterilization of the colonic contents the way was laid open to the immediate cure of certain hitherto dangerous diseases such as the bacillary dysenteries and to the mitigation of many other ulcerative diseases in which secondary bacterial infections from the faeces were an important secondary effect. In addition to the sterilization of the faeces these also became mushy in consistency and much less irritating to conditions such as diverticulitis and recent suture lines in the bowel.

The following conditions can only benefit from sterilization of the faeces: Amœbic dysentery, ulcerative colitis, diverticulitis, Crohn's disease and perirectal suppurations.

The operative surgery of the colon is robbed of all infection fears by the administration for five days of 24 grammes daily of sulphasuxidine or 12 grammes of sulphathalidine, given in divided doses at three-hourly intervals. Five days will not suffice if there is obstruction or abscess formation present. With this premedication the whole colon and not only the right half is available for one-stage resection with shorter time in hospital and no unpleasantness of temporary colostomies and Mikulicz resections.

Mr. Alan H. Hunt: My communication deals briefly with the effect of sulphasuxidine in reducing the incidence of peritonitis when given before major intraperitoneal operations on the colon and rectum.

The figures are derived entirely from Mr. Lawrence Abel's Clinic at the Royal Cancer Hospital, and I am greatly indebted to him for allowing me to analyse these cases and to present the tabulated results at this meeting.

At the Cancer Hospital we tend to get cases of a desperate nature, sent there from somewhere else and as a last hope. The fatality rate is thus not indicative of what is disclosed by an analysis of a wider range of cases: but I have limited the analysis to Cancer Hospital patients for the very good reason that we thus deal with two series of consecutive cases in which the operative technique, theatre facilities, nursing, etc., have been unchanged throughout the period of analysis.

There is only one factor which differs between the two groups of cases—the administration of sulphasuxidine pre-operatively in the second group. (There is, of course, penicillin, which became available in reasonable quantities in 1944. But we would not expect this drug to have an appreciable effect on peritoneal infections arising from faecal contamination.)

Table I shows the results before the introduction of sulphasuxidine in September 1943. I have divided the cases of carcinoma of the rectum into the four stages: Stage I limited to the rectum, II extending beyond the rectum, III with regional lymphatic metastases and IV with distant metastases. 11 of these 78 patients died, 2 of diffuse peritonitis, 1 of intraperitoneal abscess, 4 with localized peritonitis evident post mortem, and 4 of other causes.

Of 12 other cases, 4 died, 2 with diffuse and 2 with localized peritonitis.

TABLE I.—1939—AUG. 1943: BEFORE INTRODUCTION OF SULPHASUXIDINE.

Carcinoma of rectum Abdomino-perineal excision	Stage	No.	Av. age	Deaths	Age	Cause of death
	I	8	53	—		
	II	39	57.5	6	55	Pneumonia
					62	Pneumonia with local peritonitis
					61	Pneumonia with local peritonitis
					74	Heart failure with local peritonitis
					51	General peritonitis
					55	Suicide
	III	21	55	3	62	Uræmia
					54	General peritonitis
					57	Heart failure with local peritonitis
	IV	10	51	2	51	Local peritonitis with ac. dil. stomach
					62	Heart failure
Totals		78		11	Average stay in hospital of 67 survivors was 51 days	
Hartmann's operation	...	4	60	1	73	Heart failure and uræmia with local peritonitis
Colonic resection and anastomosis		6	62	3	88	Local peritoneal abscess
					60	Diffuse peritonitis
					74	Diffuse peritonitis
Palliative colonic anastomoses		2	60	—		
Totals		90		15	At death: Diffuse peritonitis ... 4 Local peritonitis ... 7	

Table II shows the results in the second group, after the preoperative administration of sulphasuxidine had become an established routine. The dose has been 50 grammes, 10 grammes given daily for five days.

TABLE II.—1944-45: AFTER INTRODUCTION OF SULPHASUXIDINE
10 gm. DAILY FOR 5 DAYS BEFORE OPERATION.

Carcinoma of rectum Abdomino-perineal excision	Stage	No.	Av. age	Deaths	Age	Cause of death
	I	5	47	1	71	Pulmonary embolus
	II	20	59	2	72	Pulmonary embolus
					62	Heart failure
	III	20	60	1	73	Pneumonia
	IV	5	61	—		
		1	66	—		
Carc. paracophoron A-P with Wertheim	Totals	51		4	Average stay in hospital of 47 survivors was 40.5 days	
Hartmann's operation and excr. with extra-peritoneal anastomosis		5	47	2	60	Heart failure with multiple metastases (stage iv)
					63	Pylonephritis and uræmia
Colonic resection and anastomosis		14	55	2	44	Obstruction from adhesion to intraperitoneal deposit
					63	Pneumonia
Palliative anastomoses	...	5	56	1	41	Extensive malignant disease
Totals		75		9	At death: Diffuse peritonitis ... 0 Local peritonitis ... 0	

Here there were but 4 deaths in 51 abdomino-perineal resections, 2 due to pulmonary embolism, 1 to heart failure and 1 to pneumonia. There was no peritonitis.

Of the remaining 24 miscellaneous cases in this table, 5 died, and again intraperitoneal infection was conspicuous by its absence.

To summarize, of the 90 cases undergoing major intraperitoneal operations on the colon before the introduction of sulphasuxidine, 15 died (a fatality rate of 16.5%), and of these 4 had diffuse and 7 localized peritonitis at death. Of the 75 cases operated on after the introduction of sulphasuxidine, 9 died (a fatality rate of 12%), and of these none had any intraperitoneal infection.

The length of convalescence after abdomino-perineal resections is a good indication of the extent of wound infection. Without sulphasuxidine, the average stay in hospital after operation was 51 days; with sulphasuxidine, 40.5 days. This reduction of ten days seems to be significant.

Section of Obstetrics and Gynæcology

President—Professor F. J. BROWNE, M.D.

[November 16, 1945]

DISCUSSION ON PLACENTA PRÆVIA

Mr. C. H. G. Macafee, in opening the discussion, described the policy of the Royal Maternity Hospital, Belfast. In 1937 it was decided to allocate the three common emergencies to three members of the visiting staff. The care of all cases of antepartum hæmorrhage was allocated to him. His remarks were based on 191 cases (including 24 private cases) from 1937 until September 30, 1945. There was one maternal death (0.52%) and 42 stillbirths and neonatal deaths (22%). When the foetal mortality was corrected by the elimination of abnormalities such as anencephaly from the stillbirths and of gastro-enteritis from the neonatal deaths it was only 18.8%.

In any case of placenta prævia the attendant who saw the patient first had a great responsibility. He must recognize that, unless in the exceptional event of a serious hæmorrhage, the patient should be removed to an institution without any vaginal examination being made. The fact that only a few patients in this series had been examined before admission must have had an important influence on the results.

The main objectives in dealing with placenta prævia were to reduce foetal mortality without unfavourably affecting the maternal condition and to keep an open mind concerning treatment. One of the main causes of foetal mortality in placenta prævia is prematurity. This can be reduced only by carrying on the pregnancy to as near full term as possible.

In support of his opinion that there is a definite place for expectant treatment in this complication he submitted the following arguments:

(1) A severe initial hæmorrhage rarely occurs apart from vaginal manipulations. The number of primigravidae, and indeed multiparæ, who proceed to full term with extreme degrees of placenta prævia without hæmorrhage is striking.

(2) Some patients have a sharp but not severe hæmorrhage at 30 to 34 weeks. Later the placenta can be palpated inside the os without provoking further bleeding, this being due to infarction of the separated area.

(3) Repeated hæmorrhages have occurred while in hospital without embarrassing mother or baby. Many patients carry out their own expectant treatment by ignoring small hæmorrhages, until one occurs which alarms them.

The attitude that a placenta prævia is not an obstetrical emergency which must receive active treatment at the first hæmorrhage has meant that the infant's chance of survival is much enhanced. Approximately 42% of the stillbirths or neonatal deaths occurred in the first two years under review, whereas in 1944 there were only three such deaths (16.6%) and in the first nine months of 1945 one death (6.4%).

The type or degree of placenta prævia has an important influence on treatment. He appealed for the removal of the terms "lateral", "marginal" and "central" from obstetric literature, the last two being inconsistently used by medical writers. Browne's classification if adopted universally would ensure uniformity. This classification, with the use of the term "type" instead of "degree", has been followed in the present paper.

Mr. Macafee went on to say that placenta prævia is usually a much larger and thinner placenta than one normally situated, and frequently has an excentric insertion of the cord. Insertion of the umbilical cord in relation to the separated area of the placenta is important and accounts for a certain unavoidable foetal mortality. If the cord is inserted at the lower edge of the placenta where the separation occurs or, if it has a velamentous insertion in this area, the child is unlikely to survive after the initial hæmorrhage.

The decision regarding a vaginal examination demands the careful consideration of an experienced obstetrician. With few exceptions a vaginal examination has been performed on all cases in this series, but only after all preparations were complete for immediately carrying out the appropriate treatment for the individual case, therefore the examination has been postponed until the termination of expectant treatment and is then made with the patient on the operating table. The cervix and the vagina should, of course, be inspected *per speculum* after the first hæmorrhage to exclude local causes of bleeding.

TABLE I.—1939—AUG. 1943: BEFORE INTRODUCTION OF SULPHASUXIDINE.

Here there were but 4 deaths in 51 abdomino-perineal resections, 2 due to pulmonary embolism, 1 to heart failure and 1 to pneumonia. There was no peritonitis.

Of the remaining 24 miscellaneous cases in this table, 5 died, and again intraperitoneal infection was conspicuous by its absence.

To summarize, of the 90 cases undergoing major intraperitoneal operations on the colon before the introduction of sulphasuxidine, 15 died (a fatality rate of 16.5%), and of these 4 had diffuse and 7 localized peritonitis at death. Of the 75 cases operated on after the introduction of sulphasuxidine, 9 died (a fatality rate of 12%), and of these none had any intraperitoneal infection.

The length of convalescence after abdomino-perineal resections is a good indication of the extent of wound infection. Without sulphasuxidine, the average stay in hospital after operation was 51 days; with sulphasuxidine, 40.5 days. This reduction of ten days seems to be significant.

there was the greatest co-operation between the obstetrician, residents and nursing staff. Given these conditions, equally good results can be achieved, using methods which may vary greatly as regards the details of obstetric treatment.

My own cases of placenta prævia were examined under a general anæsthetic with complete asepsis. The vagina was ironed out, the whole hand introduced, and the index finger passed through the cervix and the position of the placenta ascertained, care being taken to produce as little bleeding as possible. If the presenting part were a vertex, easily palpated with little disturbance of the placenta, the membranes were ruptured and nothing more done. If the presenting part were a flexed breech, the os two fingers dilated and the breech easily reached without producing much hæmorrhage, the membranes were ruptured and a foot drawn down. This treatment was mostly used where the babies were either small or dead. If after rupturing the membranes, or subsequently, a severe hæmorrhage occurred, the vagina was plugged with rolls of 6-in. gauze soaked in Dettol 5%, from 3 to 5 rolls, 6 yards in each being used, and a pad and tight binder applied. The plugging was retained the minimum time possible.

Table A gives the main results in 139 consecutive cases treated at Queen Charlotte's Hospital by all members of the staff prior to 1933. All methods of treatment were used, including vaginal plugging.

Table B shows my own series of cases similarly analysed.

TABLE A.—139 CONSECUTIVE CASES ENDING 1933

Maternal mortality rate 6.47%.			Stillbirth rate 52.5%.			Morbidity rate 14.7%.		
Complete placenta prævia—Type 3			Marginal placenta prævia—Type 2			Lateral placenta prævia—Type 1		
Total	Maternal deaths	Stillbirths	Total	Maternal deaths	Stillbirths	Total	Maternal deaths	Stillbirths
31	3 (19.3%)	22 (71%)	48	3 (6.25%)	34 (71%)	60	Nil	17 (28.3%)
All types of treatment were used.								

TABLE B.—143 CONSECUTIVE CASES (1933-1938)

Maternal mortality rate 1.4%			Stillbirth rate 58.7%			Morbidity rate 15.4%		
Complete placenta prævia—Type 3			Marginal placenta prævia—Type 2			Lateral placenta prævia—Type 1		
Total	Maternal deaths	Stillbirths	Total	Maternal deaths	Stillbirths	Total	Maternal deaths	Stillbirths
12	Nil	2 (16.6%)	79	2 (2.5%)	53 (64.6%)	52	Nil	29 (55.8%)

TABLE C.—ANALYSIS OF METHODS OF TREATMENT (1933-1938)

Method of treatment	Number of cases	Maternal deaths	Stillbirths
Artificial rupture of membranes and binder	54	Nil	21 (39%)
Bringing down leg	15	Nil	14
Cæsarean section	9	Nil	Nil
Cæsarean section after plugging	6	Nil	1
Plugging with rupture of the membranes and binder	59	2	39 (66%)

I am not an ardent supporter of vaginal plugging in the treatment of placenta prævia, though I think there are still occasions when it is difficult to avoid it. I am opposed to its use in domiciliary practice, but in hospital, with full surgical asepsis, I think it still has a place, though an occasional one, in the treatment of placenta prævia. This series shows that, in spite of opinion to the contrary, vaginal plugging properly carried out can control severe hæmorrhage in placenta prævia cases, and that sepsis when it occurs, is very moderate and can be ignored. In this series, the sepsis rate following plugging was less than 1% greater than the rate obtained in 143 consecutive cases treated by all members of the staff and by all known methods. In this series an attempt was made to get good results by obstetric methods and without doing a large number of Cæsarean sections, and I think it succeeded. Looking back on these cases I think I made four mistakes: (1) Many of them could have been left after admission until a severe hæmorrhage occurred, thus improving the foetal mortality rate. (2) All cases at the original examination should have been on the operating table of the theatre, so that a Cæsarean section could have been carried out immediately, if necessary. (3) I can now see no advantage in using dilators to establish the position of the placenta in primigravidae with a closed cervix. If a sharp hæmorrhage occurs in such cases they are best treated by a Cæsarean section, without disturbance of the placenta. (4) In another such series of cases I would plug the vagina much less frequently, and do many more Cæsarean sections.

A vaginal examination is essential because:

- (1) It is not possible to diagnose a placenta prævia on the character of the bleeding.
- (2) The diagnosis of placenta prævia should not be made unless the placenta has been felt in the lower uterine segment.
- (3) Only when the type of placenta prævia is determined can one decide upon the best method of treatment.

RESULTS OF VARIOUS METHODS OF TREATMENT

Treatment	No. of cases	Stillbirths or died	%
Artificial rupture of membranes	54	7	13
A.R.M. and Willetts forceps	21	9	42.9
Version	23	18	78.3
Cæsarean section	79	2	2.5
Breech	6	5	83.3
None	8	1	12.5

The one maternal death followed a Cæsarean section, and was due to a staphylococcal septicæmia; a maternal mortality rate for Cæsarean section of 1.27%.

Type I can usually be dealt with by rupture of the membranes.

In Type II, if the placenta lies anteriorly, artificial rupture of the membranes is usually sufficient, but if the placenta is in the posterior position a Cæsarean section is indicated.

Type III in the series was associated with the highest foetal mortality, due to the fact that hæmorrhage occurs at a much earlier period of gestation.

Type IV necessitates Cæsarean section.

In the light of the excellent results recently published, the attitude towards maternal and foetal mortality associated with placenta prævia must be revised. This mortality has been regarded as inevitable in the past. He believed it could be radically reduced. If the policy outlined could be adopted more generally he felt sure that in less than ten years results would be forthcoming which would completely eclipse the figures in this series.

The results presented were not due to the efforts of any one person but to co-operation between many: general practitioners, hospital residents and nursing personnel, blood transfusion service, anaesthetists, pædiatric department and the patient herself.

Mr. Leonard Phillips: In 1933 a scheme of allocation of cases was instituted at Queen Charlotte's Hospital, and from 1933-38 it was my privilege to treat most of the cases of placenta prævia which were admitted to the hospital. A series of 143 consecutive cases was treated with a maternal mortality rate of 1.4%.

The first factor which has helped to reduce the maternal mortality rate is the better condition in which cases are now admitted to hospital. Most practitioners now realize that cases of placenta prævia can only be treated satisfactorily in hospital, where asepsis, blood transfusions, skilled nursing and specialized obstetric help are available.

The second factor in securing good results is blood transfusion. I consider that the most important factor in securing my own results was blood transfusion. Many cases received one transfusion and some cases two or three transfusions. The majority of deaths in placenta prævia cases occur as a result of hæmorrhage. In any modern, well-staffed and well-equipped hospital a death from hæmorrhage should be rare.

The third factor which has helped to reduce the maternal mortality rate is the greatly extended scope of Cæsarean section. The following types of cases are best treated by Cæsarean section:

(1) All cases in which, at the first examination under anæsthetic, the placenta is found to cover completely the os which is one to two fingers dilated, and in which the presenting part cannot be reached without separating the placenta and causing sharp hæmorrhage.

(2) All cases in which a sharp hæmorrhage has occurred in a primigravida with an undilated cervix.

The increased consideration now given to the claims of the child is another reason for the extended use of Cæsarean section. These are the days of one-child marriages or spaced children, the child may be the first after ten years of marriage, and the mother may demand a Cæsarean section; we are all very much aware of the psychological damage to the mother following the loss of a child for which she has waited many years, and finally, the methods now employed in rearing premature babies have greatly improved. If therefore the fœtus is 36 weeks mature and alive at the first examination under anæsthetic, there is usually a strong case for Cæsarean section, apart from the maternal indications.

The fourth factor responsible for improved results is team work. In my own cases

unless there is severe hæmorrhage. All patients, however slight the hæmorrhage, are advised to remain in hospital until confinement.

The chief justification for expectant treatment is that it gives the fœtus a chance of reaching maturity. For cases of placenta prævia, it is now established that Cæsarean section offers the best chance for the fœtus and it is taking an increasingly important place in the treatment of these cases.

We have found little difficulty in persuading patients to remain in hospital for the long periods, eight or even ten weeks, that may be necessary. Shortage of hospital beds should not be admitted as a reason for not giving expectant treatment. Antepartum hæmorrhage is one of the gravest of all obstetric emergencies and requires the best treatment.

TABLE II—MATERNAL AND FETAL MORTALITY IN ANTEPARTUM HÆMORRHAGE

				(Excluding extra-placental lesions)			
Mothers	517	Mothers	498
Maternal deaths	14	Maternal deaths	14

Infant mortality	24 out of 67					= 35.6%				

Professor James Young said that the main conclusion from Mr. Macafee's paper was the considerable reduction in fetal mortality which could be obtained by the extension of the expectant treatment of placenta prævia and without any addition to the maternal risk. Professor Young recorded the results of ten years' experience at the British Post-

Miss Josephine Barnes (*Abridged*): It is proposed to deal with the subject of placenta prævia in relation to the general problem of antepartum hæmorrhage. Between the years 1927 and 1944 inclusive, 538 cases of antepartum hæmorrhage have been admitted to the Obstetric Hospital, University College Hospital. These cases are now classified into four groups as follows:—

	TABLE I						
	Total	538	
Delivered elsewhere	21
(1) Placenta prævia	140
(2) Accidental antepartum hæmorrhage	73
(3) Antepartum hæmorrhage of uncertain origin	285
(4) Antepartum hæmorrhage from extraplacental lesions	19

No case is accepted as one of placenta prævia unless the placenta is either felt from below with a finger passed through the cervix or is found to be in the lower segment at abdominal section. The appearance of the placenta after delivery and the clinical features of the case are not accepted as evidence of placenta prævia.

Similarly, no case is defined as accidental antepartum hæmorrhage unless the absence of the placenta from the lower segment is confirmed either by thorough digital exploration from below or at abdominal section. The occurrence of concealed hæmorrhage, while denoting in most cases that the placenta is in the upper segment is not in itself diagnostic since concealed hæmorrhage may occur in placenta prævia.

The adoption of this strict classification has meant that more than half of our cases fall into the group of antepartum hæmorrhage of uncertain origin, and the adoption of a more expectant attitude to cases of antepartum hæmorrhage has led to an increased proportion of cases in this group.

Lesions of the cervix and vagina are diagnosed at the routine examination with a speculum, which is performed when the patient is admitted. It must be emphasized that the presence of, say, a vascular erosion of the cervix does not necessarily exclude a more grave cause for the hæmorrhage.

Four cases of abortion, three of placenta prævia and one of concealed hæmorrhage occurring at the 22nd week are included.

The general maternal mortality for the whole series was 2.7% and the uncorrected foetal mortality was 36.9%.

In the 140 cases of placenta prævia, the maternal mortality was 2.9% and the foetal mortality 52.2%. More detailed analysis shews that out of the 71 infants lost, 38 were lost following the bringing down of a leg to check hæmorrhage. The majority of these cases occurred early in the series and the method has largely been abandoned in recent years.

For the classification of cases of placenta prævia we have used that originally suggested in 1929 by Mr. Norman White. This divides cases of placenta prævia in accordance with the situation of the placenta into four types or degrees. It is suggested that this classification should be universally adopted. It is interesting to note that, so far, the best results have been obtained in cases of fourth degree placenta prævia, largely due to the high incidence of Cæsarean section in the treatment of these cases.

Four mothers lost their lives as a result of placenta prævia, one died from hæmorrhage and shock following a bougie induction and placenta prævia was not diagnosed until autopsy. One died of pulmonary embolism on the seventeenth day after Cæsarean section. The third patient died of shock and hæmorrhage after treatment with Willett's forceps. The fourth patient died of septicæmia due to uterine infection with *Clostridium welchii*. This followed treatment with Willett's forceps and the occurrence of this case and a second similar one where the patient recovered has led to the abandonment of Willett's forceps for the treatment of placenta prævia.

Analysis of the causes of foetal death reveals two main causes—prematurity and placenta separation causing antepartum or intrapartum asphyxia. Cerebral hæmorrhage was found in some cases.

In order to improve the results to mother and infant, certain general principles can be laid down. The first is avoidance of sepsis and the second, preparations to combat hæmorrhage. This means that such cases should never be dealt with outside a properly equipped institution and that a patient suffering from antepartum hæmorrhage should be transferred to hospital at once without any vaginal examination being made.

Once the patient has been admitted, she should be treated expectantly. A speculum is passed and preparations are made for transfusion, but no vaginal examination is made

of their infants was 6 lb. 7 oz. The mothers of the remaining 16 surviving infants, however, had had an average of 1.5 recurrent hæmorrhages during an average period of expectancy of 25.5 days; the average weight of their infants was 5 lb. 15 oz.

In the light of experience acquired in expectant treatment the stillbirths and neonatal deaths of the *whole series* had been reviewed. In the case of 4 stillborn infants and 7 who died their mothers might have been treated expectantly instead of actively on admission. In the case of a further 3 in each of these classes their mothers ought to have been treated expectantly.

Mr. Purdie thanked his colleagues, Mr. K. A. K. Hudson and Mr. D. Friedlander, who allowed him to include cases treated by them.

Comment (A. W. P.).—In any attempt to reduce the maternal and foetal death-rate from placenta prævia the training of the midwife is of great importance. The doctor is criticized if he makes a vaginal examination before sending the patient into hospital. Yet the textbooks for midwives and pupil-midwives still advocate the rupture of membranes by midwives in certain circumstances. Moreover at the examinations conducted by the Central Midwives Board candidates are still expected, by some examiners, to say that they would rupture the membranes themselves. Is it not time that this teaching was altered?

Mr. Rufus C. Thomas supported Mr. Macafee's contention that placenta prævia was not an obstetrical condition which must necessarily be dealt with at the first hæmorrhage. He had adopted this attitude since 1937, during which time 182 cases had been treated. Many of them had been kept in hospital from two to ten weeks before being finally dealt with. The influence of such delay on the chances of survival of the foetus was shown by the fact that of the 182 cases, 125 were dealt with after the 38th week, and a further 25 cases between the 36th and 38th week. The foetal mortality for the whole series was 23%. Two mothers were lost, but neither died from hæmorrhage. One died of pulmonary embolism on the 11th day after Cæsarean section. The other was a case of eclampsia with central placenta prævia, who died in coma shortly after Cæsarean section.

Methods of treatment were on the same lines as those outlined by Mr. Macafee. During the period of expectancy, patients were blood-grouped, hæmoglobin estimations done, and transfusions carried out if necessary. Apart from routine inspection of the cervix, nothing further was done, unless hæmorrhage forced the issue, until the time came for the full examination under anaesthesia. This was carried out in the theatre, with all preparations for the Cæsarean section which might be found necessary. Each patient was assessed for treatment individually.

Willett's forceps were used in 9 cases, and vulsellum forceps in 38 cases, with an infant mortality of 12.8%. No weight was attached to the forceps, traction being only applied if bleeding occurred, and this was released when the bleeding was controlled. It was thought that this intermittent pressure on the placenta enhanced the chances of the foetus. Cæsarean section had been performed in 63 cases.

Internal podalic version had only been used in cases of prolapse of the arm or transverse lie. The mortality had been 100%. 7 cases had been delivered by the breech, this being the presentation on admission. The foetal mortality was 57%, and it was suggested that Cæsarean section should be done in such cases, especially in primigravidae, as the foetal mortality in breech deliveries was so high.

Mr. J. Stallworthy reported 119 consecutive cases of placenta prævia treated at the Radcliffe Infirmary, Oxford, without a maternal death. He welcomed Mr. Macafee's suggestion that the old classification of placenta prævia be scrapped but he advocated that in a case of antepartum hæmorrhage much greater importance should be given to the position of the baby than to the position of the placenta. He felt this was a reform in obstetrical teaching and practice long overdue. He emphasized the importance of the placenta situated posteriorly in the lower uterine segment and illustrated this by a black-board sketch to show how in such cases the true conjugate was shortened by the width of placenta lying over the promontory. This position of placenta was not uncommon and in his series of cases in 31 treated by Cæsarean section 14 had this type of placenta. Unless its importance was recognized it was most dangerous as it so often arrested descent of the presenting part and by making hæmorrhage difficult to control placed both mother and infant in grave danger. In his opinion this type of case with the head above the brim should be treated by Cæsarean section.

The President said it was evident from the figures presented by Mr. Macafee that if the foetus was alive and viable one of two methods of active treatment of placenta prævia should be adopted, i.e. rupture of membranes or Cæsarean section. Podalic version

graduate Medical School, Hammersmith Hospital. In 108 cases of placenta prævia the foetal mortality was 19·4%; 33 had been treated expectantly with a foetal mortality of 9%. During the first six years the total infant mortality (stillbirths and neonatal) was 29·2%, but with increasing resort to expectancy in the last five years this had been reduced to 13·4%. In 77 booked cases the infant mortality was for the whole period 13%.

Professor Young pointed out that, where the antepartum bleeding was due to accidental hæmorrhage, expectant treatment had not reduced the infant loss. In a total of 162 cases the infant mortality was 32·7%. Of these 43 had been treated expectantly with a combined stillbirth and neonatal mortality rate of 30·2%.

Professor Munro Kerr: I am in the unique position of being able to recollect the ridicule that was hurled against Lawson Tait in the late eighties of the last century, when he proposed Cæsarean section for placenta prævia. The pendulum has made its full swing. The question today is not under what circumstances Cæsarean section should be performed for placenta prævia, but rather under what circumstances the operation of Cæsarean section should *not* be performed for this complication.

It would appear that there remain really only two methods of treatment for placenta prævia, provided the patient is in an institution and has not to be treated in unfavourable surroundings, when of course the best in the circumstances must be done, which is probably podalic version and bringing down a foot for the graver forms of the complication.

The alternatives are rupture of the membranes for the slighter cases of lateral placenta prævia and Cæsarean section for all others. But even if rupture of the membranes is performed in this limited group, the foetal mortality rate is something like 15% to 20%, and with little prospect of reducing it.

Most important is the matter that has been stressed by several speakers and particularly by Mr. Macafee that everything must be done to carry on the pregnancy to as near term as possible, in order to reduce the foetal mortality from prematurity to its lowest limits. Then, when the child has reached anything over the 36th week, Cæsarean section will undoubtedly save the greatest number of infants, without unduly risking the mother's life.

Professor Munro Kerr was very hopeful that by some means it would be possible to improve the technique for localizing the position of the placenta by radiography. It would be of enormous advantage in cases of uterine hæmorrhage in the later months, if the exact position of the placenta could be located.

Mr. A. W. Purdie said that in the maternity department of the North Middlesex County Hospital during the years 1940 to 1944 inclusive there had been 143 cases of placenta prævia among 6,921 deliveries.

There had been 1 maternal death (0·69%). This occurred in an "emergency" case of lateral placenta prævia (Type I). Cæsarean section had been performed as artificial rupture of the membranes (cervix one fingerbreadth dilated) failed to arrest the hæmorrhage. The uterus had been atonic, never really contracting well. Hæmorrhage recurred at the close of the operation, and she died shortly afterwards in spite of continuation of the blood transfusion and packing the uterus. This death might perhaps have been avoided if, before closing the abdomen, hysterectomy had been performed.

Of 147 infants born, 100 (68·03%) remained alive, 20 (13·60%) were stillborn and 27 (18·36%) died. The combined foetal mortality was 47 (31·97%). No eliminations were made on account of prematurity as this was considered to be due to the maternal placenta prævia.

EXPECTANT TREATMENT

With the more liberal use of blood transfusion and Cæsarean section there had been improvement in recent years in both maternal and foetal results. Further improvement in the latter seemed to lie in expectant treatment of the maternal hæmorrhage—where that was possible without increasing the maternal risk.

Expectant Treatment in this Series

Forty-one cases had been treated expectantly over periods varying from 12 hours to 67 days. The majority of these had been treated, at the end of the waiting period, by artificial rupture of the membranes or Cæsarean section (with or without examination under anaesthesia) or had gone into labour spontaneously and had required no treatment.

No maternal death had occurred in any case treated expectantly.

Of 43 infants born to these mothers 32 (74·4%) had survived finally, 5 (11·6%) were stillborn and 6 (14%) died. The mothers of 16 of the surviving infants had had no recurrent hæmorrhages in an average waiting period of 19·75 days: the average weight

in the glomerulus of the kidney. At the distal end of the capillary the hydrostatic pressure of the blood has been dissipated in friction and, being now below the colloid osmotic pressure of the plasma proteins, is low enough to allow tissue fluid to enter the plasma. If the blood were stationary, exchange of solutes would still take place through the capillary wall, e.g. glucose would still diffuse from plasma to tissue fluid and urea from tissue fluid to plasma, but the actual ebb and flow of fluid, which is a consequence of the mechanical features of the circulation and which must materially assist in metabolic exchange, would be absent.

Factors maintaining an equilibrium between plasma and tissue fluid which are rather more difficult to assess concern the permeability of the capillary wall to protein, and the actual mechanical pressure existing in the tissues. With regard to the first point it is well known that tissue fluid contains a trace of protein and that this may, in some circumstances, increase, and it is questionable whether the permeability of the capillary wall is a constant factor. With regard to the second point, it is clear that filtration through the walls of the capillaries in the general tissues of the body is not strictly comparable to that in the glomerulus of the kidney for two reasons. First, the hydrostatic pressure is lower, and secondly, instead of the filtrate being freely drained away by the tubule, it is being driven into a space which is already "full". There must, therefore, be a mechanical obstruction to filtration should anything occur to lessen the return of tissue fluid to the blood stream either directly or through the lymphatics. It is possible to do little in the way of measuring these two factors, but they must be borne in mind.

It is taken for granted that the osmotic pressure of all the fluid compartments is the same, and it may be assumed for all practical purposes that if the osmotic relations between intracellular and extracellular fluid are disturbed, equalization can be achieved in the first instance only by passage of water through the cell membrane which is impermeable to the majority of ions. The osmotic pressures thereby become equalized at a somewhat abnormal level. Such transfers of fluid may be minimized by purely extracellular adjustments. Thus, if the extracellular fluid became more dilute than the intracellular fluid, the requirements of osmotic equilibrium would result in passage of water into the cells, but this could be rapidly corrected by either excretion of the excess water or retention of sodium chloride by the kidneys. The sodium chloride would be confined to the extracellular fluid, and would enable all the retained water to be accommodated in this compartment without disturbing the osmotic pressure inside the cells. However, the volume of the extracellular compartments would be increased.

In order to estimate the total volume of extracellular fluid, it is necessary to find a substance which is readily diffusible through the capillary endothelium, which will not diffuse into the cells of the body, and which is sufficiently slowly excreted to enable it to become evenly distributed. Sodium thiocyanate fulfils these requirements very closely, and the degree to which a measured amount becomes diluted when introduced into the body furnishes a measure of the volume of the combined extracellular compartments. To obtain the volume of plasma it is necessary to inject into the blood stream a substance which is not diffusible through the capillary endothelium, but whose molecules are not sufficiently large to be attractive to the reticulo-endothelial system. The substance generally used is Evans Blue, and dilution of a given amount enables the plasma volume to be computed. By difference the volume of the interstitial fluid is found.

The state of affairs in pregnancy.—It has long been assumed that water retention takes place in pregnancy, but until methods for the quantitative assessment of body water became available this was not easy to prove. The comparison of intake and output is difficult on both technical and theoretical grounds. Technically, on account of the water associated with every article of diet and on account of the loss of water by evaporation, and theoretically, because of the interconversion of the three main types of food-stuff with consequent variations in metabolic water in a subject whose weight is steadily increasing.

Various balance experiments have been carried out on the inorganic constituents of the diet, and there can be little doubt that a retention of sodium occurs during the latter part of pregnancy and perhaps throughout its course. The findings of five sets of investigators are summarized by Chesley (1944), and they show a gain of from 1.6 to 8.8 grammes of sodium per week. A representative figure would seem to be about 3 grammes. If all this sodium were osmotically active, about a litre of water a week would have to be accommodated in the extracellular compartments in order to maintain the osmotic pressure of the body fluids at a normal level. Although the various researches covered only a few weeks, the inference is inescapable that such a retention

and bringing down a foot, or bringing down a foot if the breech presented, resulted in a foetal mortality that was far too high, and the same was true of Willett's forceps. Artificial rupture of membranes should, however, only be carried out if good contractions were present and the os dilating. He thought that location of the placental site by injecting a radiopaque substance into the amniotic cavity was of little value in diagnosis, for it induced premature labour in about half the cases and could not therefore be used till after the 36th week, and it might even cause intrauterine death of the foetus. In one of his cases its use resulted in a pus-discharging sinus communicating with the amniotic cavity and though the patient recovered it caused considerable anxiety. Most of the cases of antepartum hæmorrhage treated expectantly went into labour spontaneously at term and gave birth to a living child without further bleeding or any interference, and the cause of the hæmorrhage then remained undiagnosed. Such cases appeared in the hospital report as "antepartum hæmorrhage of doubtful origin" and each year formed by far the largest group. In backward countries such as Professor Nixon had described one must do the best one could in the circumstances and no doubt podalic version and extracting a foot might there be a useful measure. The question was sometimes put to him by students: "What is one to do in a case of severe A.P.H. 20 miles from a hospital? Should not the vagina be plugged before moving the patient?" His own experience was that bleeding had always ceased when one got to the house. Plugging the vagina would almost certainly start a fresh hæmorrhage. It was better to give $\frac{1}{2}$ grain of morphia and as soon as the patient had recovered sufficiently from shock to transfer her to hospital without any further interference. He did not think there was any place for the use of the vaginal plug in the hospital or outside.

In reply to the President, Mr. Phillips stated that the methods he used, including plugging, were the result of an attempt to try to obtain good results as far as the mother was concerned, more or less ignoring the foetus, and by using obstetric methods rather than Cæsarean section.

Only 10% of the cases were treated by Cæsarean section, yet the maternal mortality rate was only 1.4%. He thought that there was still a use for vaginal plugging, though a much less frequent use than in the past. He also thought that by increasing the number of Cæsarean sections, a much lower foetal mortality rate would be obtained.

DISCUSSION ON BACTERIÆMIA IN PUERPERAL SEPSIS

Openers: Mr. James Wyatt, Dr. R. Cruickshank and Dr. A. M. Ramsay.

There was a lengthy discussion in which many other speakers took part (see *Brit. med. J.*, 1946 (i) 175; *Lancet*, 1946 (i) 163).

[February 15, 1946]

DISCUSSION ON WATER METABOLISM IN PREGNANCY

Professor W. H. Newton: *The water compartments of the body.*—The water of the body is now conventionally divided into three compartments—intracellular water, interstitial or tissue fluid, and blood plasma. The ions (for instance, potassium and phosphate) which predominate in solution in the intracellular water are so different from those (for instance, sodium and chloride) which are common to the interstitial fluid and blood plasma, that the cell membrane is clearly the most important barrier. The fluid in the last two compartments is so similar that they may be regarded as sub-divisions of a single larger compartment, the extracellular fluid. The extracellular fluid may be looked upon as the *milieu interne* of Claude Bernard, and the circulation of the blood as a means of stirring it. Since the walls of the capillary blood-vessels are thought to be permeable to all constituents of the blood plasma with the exception of the plasma proteins, it follows that if the plasma proteins were absent the circulatory system could scarcely be regarded as closed, and an effective circulation would be difficult if not impossible to maintain. The function of the plasma proteins is, in virtue of their osmotic pressure, to hold a certain amount of fluid together with its solutes within the circulatory channels. According to the well-known theory of Starling, the mechanical pressure whose primary object is to circulate the blood is still, at the proximal end of the capillary, greater than the osmotic pressure of the plasma protein, and is able to drive a protein-free filtrate through the capillary walls in much the same way as occurs

in the glomerulus of the kidney. At the distal end of the capillary the hydrostatic pressure of the blood has been dissipated in friction and, being now below the colloid osmotic pressure of the plasma proteins, is low enough to allow tissue fluid to enter the plasma. If the blood were stationary, exchange of solutes would still take place through the capillary wall, e.g. glucose would still diffuse from plasma to tissue fluid and urea from tissue fluid to plasma, but the actual ebb and flow of fluid, which is a consequence of the mechanical features of the circulation and which must materially assist in metabolic exchange, would be absent.

Factors maintaining an equilibrium between plasma and tissue fluid which are rather more difficult to assess concern the permeability of the capillary wall to protein, and the actual mechanical pressure existing in the tissues. With regard to the first point it is well known that tissue fluid contains a trace of protein and that this may, in some circumstances, increase, and it is questionable whether the permeability of the capillary wall is a constant factor. With regard to the second point, it is clear that filtration through the walls of the capillaries in the general tissues of the body is not strictly comparable to that in the glomerulus of the kidney for two reasons. First, the hydrostatic pressure is lower, and secondly, instead of the filtrate being freely drained away by the tubule, it is being driven into a space which is already "full". There must, therefore, be a mechanical obstruction to filtration should anything occur to lessen the return of tissue fluid to the blood stream either directly or through the lymphatics. It is possible to do little in the way of measuring these two factors, but they must be borne in mind.

It is taken for granted that the osmotic pressure of all the fluid compartments is the same, and it may be assumed for all practical purposes that if the osmotic relations between intracellular and extracellular fluid are disturbed, equalization can be achieved in the first instance only by passage of water through the cell membrane which is impermeable to the majority of ions. The osmotic pressures thereby become equalized at a somewhat abnormal level. Such transfers of fluid may be minimized by purely extracellular adjustments. Thus, if the extracellular fluid became more dilute than the intracellular fluid, the requirements of osmotic equilibrium would result in passage of water into the cells, but this could be rapidly corrected by either excretion of the excess water or retention of sodium chloride by the kidneys. The sodium chloride would be confined to the extracellular fluid, and would enable all the retained water to be accommodated in this compartment without disturbing the osmotic pressure inside the cells. However, the volume of the extracellular compartments would be increased.

In order to estimate the total volume of extracellular fluid, it is necessary to find a substance which is readily diffusible through the capillary endothelium, which will not diffuse into the cells of the body, and which is sufficiently slowly excreted to enable it to become evenly distributed. Sodium thiocyanate fulfils these requirements very closely, and the degree to which a measured amount becomes diluted when introduced into the body furnishes a measure of the volume of the combined extracellular compartments. To obtain the volume of plasma it is necessary to inject into the blood stream a substance which is not diffusible through the capillary endothelium, but whose molecules are not sufficiently large to be attractive to the reticulo-endothelial system. The substance generally used is Evans Blue, and dilution of a given amount enables the plasma volume to be computed. By difference the volume of the interstitial fluid is found.

The state of affairs in pregnancy.—It has long been assumed that water retention takes place in pregnancy, but until methods for the quantitative assessment of body water became available this was not easy to prove. The comparison of intake and output is difficult on both technical and theoretical grounds. Technically, on account of the water associated with every article of diet and on account of the loss of water by evaporation, and theoretically, because of the interconversion of the three main types of food-stuff with consequent variations in metabolic water in a subject whose weight is steadily increasing.

Various balance experiments have been carried out on the inorganic constituents of the diet, and there can be little doubt that a retention of sodium occurs during the latter part of pregnancy and perhaps throughout its course. The findings of five sets of investigators are summarized by Chesley (1944), and they show a gain of from 1.6 to 8.8 grammes of sodium per week. A representative figure would seem to be about 3 grammes. If all this sodium were osmotically active, about a litre of water a week would have to be accommodated in the extracellular compartments in order to maintain the osmotic pressure of the body fluids at a normal level. Although the various researches covered only a few weeks, the inference is inescapable that such a retention

would more than account for the average observed gain in weight during pregnancy. So far as it is possible to draw conclusions from average figures obtained by different observers under different conditions, it would appear that the sodium is not all osmotically active. Nevertheless, it is reasonable to suppose that some of it is, and Thompson and Pommerenke (1939) have shown that fluctuations in the sodium and chloride balances are parallel. Moreover, Freyberg, Reekie and Folsome (1938) showed that the administration of sodium chloride for a few days during pregnancy was accompanied by an increase of body-weight, and that on withdrawing sodium chloride the weight was again reduced. Their estimations of water balance showed clearly that the variations in body-weight were due to retention and excretion of water. Their calculations of total water exchange in one subject during the last three months of pregnancy indicated a retention of only 600 grammes, but their patient had the lowest of the positive sodium balances recorded by Chesley in his review.

If salt and water retention are related in the way we have suggested we should expect to find an increase in the plasma volume and in the interstitial fluid during pregnancy, and these have actually been established. The increase in plasma volume has been confirmed by too many observers to quote (*see* Dieckmann & Wegner, 1934), but recent investigators are Mull and Bill (1945) and Albers (1939). The increases are between 20 and 30%. Chesley (1943) found the total gain of extracellular water during pregnancy to average 6.3 litre, of which 1.5 to 2 litres were probably in the products of conception, 0.7 litre in the new tissue of the uterus and breasts, and 1.3 litres in the blood plasma. This leaves about 2.5 litres (5.5 pounds) as the share of the extra-genital interstitial fluid. Since the volume of the interstitial or tissue fluid of the normal individual is probably more than four times the volume of the plasma this estimate of Chesley's is lower than we should expect, even if the uterus and breasts are included, and it is natural to look for further factors leading to selective retention of water in the plasma. Instead, we find factors operating in the reverse direction. The first of these is a drop which may be as much as 20% in the colloid osmotic pressure of the plasma due to a diminution in the concentration of plasma proteins. It is to be presumed that an additional volume of water in the extracellular fluid would be divided between its two compartments in the ratio of their original volumes, only if the conditions determining the ratio remained unaltered. The chief condition, as we have seen, is the concentration of plasma proteins, and its diminution should lead to the interstitial fluid compartment receiving rather more than its share of the excess water. In pregnancy with oedema, according to Albers, the plasma protein is yet further reduced and an increase in the protein content of the tissue fluid makes the effective colloid osmotic pressure of the plasma still lower.

Another factor is the increase in the venous pressure in the legs which has been convincingly demonstrated by McLennan (1943). He followed the pressure in the femoral vein throughout pregnancy by measurements in 255 women. The measurements were made by entering the vein and reading the pressure directly from a manometer with the subjects recumbent. The average rise was from 9 cm. of water in early pregnancy to about 24 cm. at term. This rise, which does not take place in the antecubital vein, may be due either to external pressure on the great veins within the abdomen, or to a large inflow from the uterine veins having the effect of obstructing the inflow from the legs. As the legs constitute 37% of the body-weight, the consequent increase in filtration pressure in the capillaries must drive an appreciable amount of fluid from the plasma into the interstitial fluid compartment. This might, however, be limited by an increase of pressure within the tissues themselves. Investigations of a third factor in normal pregnancy—the permeability of the capillary walls—yield results which tend to be unconvincing, but no one has yet alleged that the permeability is diminished.

We are, therefore, faced with the situation that an increase in water content of the plasma and interstitial fluid during pregnancy has been demonstrated, but that the distribution of the fluid between these two compartments is not fully accounted for. It will be noticed that the relation between the total 6.3 litres of extracellular fluid and the 1.3 litres attributed to blood plasma is not unlike that obtaining between the normal extracellular fluid and plasma volumes. There may be a fallacy in Chesley's assumption that so much of the thiocyanate-available water is in the products of conception, or pregnancy may introduce an error into the method of estimating blood volume. Added to these difficulties is the fact that evidence of an increase in the water content of any isolated organ or tissue in pregnant animals is lacking.

In an attempt to account for the retention of sodium and water during pregnancy, Taylor, Warner & Welsh (1943) administered oestrogens and progesterone to

their subjects and achieved some success in showing that this, in fact, led to such retention. It is certainly true, as they point out, that the pregnant woman is exposed to the action of these hormones in large quantities during pregnancy, and they are known from the work of Zuckerman, Palmer and Bourne (1939) and others to cause accumulation of water in certain situations in monkeys.

The weight changes of pregnancy are of great interest but not very helpful in this connexion. It seems certain that most animals increase the weight of their own extra-genital tissues during pregnancy, and Van Wagenen and Newton (1943) have shown that after removal of the foetus, provided the placenta is left attached to the uterus, the macaque monkey may resume its normal gain in weight until it delivers the placenta at term. There can be little doubt, however, from a study of Chesley's review, that if average figures are to be used as a basis for computation, either the nitrogen (if built into protoplasm) or the sodium (if osmotically active) which are retained during human pregnancy would be sufficient to account for the gain in weight. It must be admitted that the quantitative balance sheet of the various maternal gains during pregnancy leaves much to be desired, and that average figures are not a very satisfactory foundation on which to build.

Mr. G. W. Theobald: A man may live for over six weeks without food, but deprive him of water and he will die within from twenty-four hours to just over a week, depending on the temperature and humidity of his environment, and the amount of work he does. Every active cell of the human body is bathed by the interstitial fluid from which it derives its nourishment and into which it discharges its waste products of metabolism. This fluid, moreover, forms the reservoir on which the body draws for considerable supplies with which to fashion the gastric, pancreatic and other juices and secretions of the body, the sweat necessary for the regulation of its temperature, and the solvent for the waste products excreted through the kidneys.

The amount of this fluid varies within considerable limits. If water is withheld this supply is first drawn upon before the cells and blood plasma are required to part with their water. Nevertheless the red blood cell count may exceed 6 million per cubic millimetre before serious symptoms occur (Allison and Critchley, 1943). On the other hand an excess of fluid in the tissues may cause cerebral convulsions or acute oedema of the lungs. It must therefore be conceded that the control of the water balance of the body is the most important function subserved by the kidneys.

Every active cell in the body is freely permeable to water, but in no case do its organic salts bear any relation to those of its environment. It is thus evident that the higher forms of life are dependent on the selective permeability of the membranes of the cells of which they are composed. The heart pumps some 5 litres of blood through the arteries every minute, so that the speed of the circulation must be very considerable. It is therefore proper and important to regard the interstitial fluid as a constantly agitated fluid which is frequently changed.

It is generally assumed that the average man drinks some 1,500 c.c. of water and absorbs a further 800 c.c. with his food each day. Oxidative processes result in the formation of about 300 c.c. during the same period of time. He excretes approximately 1,500 c.c. as urine, 600 c.c. through his skin, 400 c.c. through his lungs, and 100 c.c. in his faeces. During exercise in hot weather several litres of water may be lost through the skin, and similar amounts may be passed through the bowel during an attack of diarrhoea. The body must provide this water but neither the skin, nor the lungs, nor the bowel can be considered in any way responsible for regulating the water balance of the body.

The body's need for water is signalled by the sensation of thirst which in extreme cases has been described as "the devouring fire of thirst, of all human wants the most insupportable and the most pressing".¹ This has been thought to be normally

¹Narrative of the loss of the *Fattysalam*, quoted by Allison and Macdonald Critchley.

would more than account for the average observed gain in weight during pregnancy. So far as it is possible to draw conclusions from average figures obtained by different observers under different conditions, it would appear that the sodium is not all osmotically active. Nevertheless, it is reasonable to suppose that some of it is, and Thompson and Pommerenke (1939) have shown that fluctuations in the sodium and chloride balances are parallel. Moreover, Freyberg, Reekie and Folsome (1938) showed that the administration of sodium chloride for a few days during pregnancy was accompanied by an increase of body-weight, and that on withdrawing sodium chloride the weight was again reduced. Their estimations of water balance showed clearly that the variations in body-weight were due to retention and excretion of water. Their calculations of total water exchange in one subject during the last three months of pregnancy indicated a retention of only 600 grammes, but their patient had the lowest of the positive sodium balances recorded by Chesley in his review.

If salt and water retention are related in the way we have suggested we should expect to find an increase in the plasma volume and in the interstitial fluid during pregnancy, and these have actually been established. The increase in plasma volume has been confirmed by too many observers to quote (*see* Dieckmann & Wegner, 1934), but recent investigators are Mull and Bill (1945) and Albers (1939). The increases are between 20 and 30%. Chesley (1943) found the total gain of extracellular water during pregnancy to average 6.3 litre, of which 1.5 to 2 litres were probably in the products of conception, 0.7 litre in the new tissue of the uterus and breasts, and 1.3 litres in the blood plasma. This leaves about 2.5 litres (5.5 pounds) as the share of the extragenital interstitial fluid. Since the volume of the interstitial or tissue fluid of the normal individual is probably more than four times the volume of the plasma this estimate of Chesley's is lower than we should expect, even if the uterus and breasts are included, and it is natural to look for further factors leading to selective retention of water in the plasma. Instead, we find factors operating in the reverse direction. The first of these is a drop which may be as much as 20% in the colloid osmotic pressure of the plasma due to a diminution in the concentration of plasma proteins. It is to be presumed that an additional volume of water in the extracellular fluid would be divided between its two compartments in the ratio of their original volumes, only if the conditions determining the ratio remained unaltered. The chief condition, as we have seen, is the concentration of plasma proteins, and its diminution should lead to the interstitial fluid compartment receiving rather more than its share of the excess water. In pregnancy with oedema, according to Albers, the plasma protein is yet further reduced and an increase in the protein content of the tissue fluid makes the effective colloid osmotic pressure of the plasma still lower.

Another factor is the increase in the venous pressure in the legs which has been convincingly demonstrated by McLennan (1943). He followed the pressure in the femoral vein throughout pregnancy by measurements in 255 women. The measurements were made by entering the vein and reading the pressure directly from a manometer with the subjects recumbent. The average rise was from 9 cm. of water in early pregnancy to about 24 cm. at term. This rise, which does not take place in the antecubital vein, may be due either to external pressure on the great veins within the abdomen, or to a large inflow from the uterine veins having the effect of obstructing the inflow from the legs. As the legs constitute 37% of the body-weight, the consequent increase in filtration pressure in the capillaries must drive an appreciable amount of fluid from the plasma into the interstitial fluid compartment. This might, however, be limited by an increase of pressure within the tissues themselves. Investigations of a third factor in normal pregnancy—the permeability of the capillary walls—yield results which tend to be unconvincing, but no one has yet alleged that the permeability is diminished.

We are, therefore, faced with the situation that an increase in water content of the plasma and interstitial fluid during pregnancy has been demonstrated, but that the distribution of the fluid between these two compartments is not fully accounted for. It will be noticed that the relation between the total 6.3 litres of extracellular fluid and the 1.3 litres attributed to blood plasma is not unlike that obtaining between the normal extracellular fluid and plasma volumes. There may be a fallacy in Chesley's assumption that so much of the thiocyanate-available water is in the products of conception, or pregnancy may introduce an error into the method of estimating blood volume. Added to these difficulties is the fact that evidence of an increase in the water content of any isolated organ or tissue in pregnant animals is lacking.

In an attempt to account for the retention of sodium and water during pregnancy, Taylor, Warner & Welsh (1943) administered oestrogens and progesterone to

be true it is evident that the hydræmic state lessens the number of red blood corpuscles lost during delivery and favours an easy return to the normal blood count when the vascular bed once again returns to its former size.

On the other hand the dilution of the blood lowers the effective osmotic pressure of the plasma colloids and thereby facilitates the escape of fluid from the capillaries to the tissue spaces. This increased loss of fluid from the arterial end of the capillary will clearly cause a correspondingly enhanced concentration of the plasma colloids at the other end of the capillary, and consequently prevent any progressive loss of fluid to the tissues. It is of course important to make sure that the woman's intake of first class proteins is adequate throughout the course of pregnancy, otherwise the effective osmotic pressure of the plasma colloids will fall still further.

The storage of sodium.—It is believed that the increase in the amounts of the sex steroids circulating in the blood is responsible for the storage of nitrogen, sodium and other substances during pregnancy. Heilig (1924) was the first to call attention to a disturbance in the water metabolism at the time of menstruation. Thorn, Nelson and Thorn (1938) found that œstrone, progesterone, pregnandiol and testosterone induced retention of sodium chloride and water in normal dogs. They further reported that sodium chloride and water were retained during both the intra- and the pre-menstrual phase of the cycle in man, and that the onset of menstruation was associated with an increased renal excretion of these substances.

If these facts be accepted the difficulty to be faced is not whether the stored sodium could cause water retention but why every pregnant woman does not drown in her own interstitial fluid. The estimates of the amounts of sodium retained during pregnancy vary from 0.23 to 1.26 grammes *daily*. If it be assumed that this sodium is osmotically active and is held extracellularly it would involve the retention of from 500 to 2,600 c.c. of water *each day*. Further Hummel *et alia* (1936) found that a nursing mother retained 22 to 27 grammes of sodium in a period of forty-three days. We know, moreover, that the postpartum diuresis occurs while the blood is still hydræmic, and while the excess sodium is still in the tissues. It may therefore be asserted with confidence that neither of these factors, nor both of them acting in concert can be the sole or even the determining factor in causing water retention during pregnancy. The sodium must be stored for the most part in an osmotically inactive form in the tissues.

The increase in weight during the course of pregnancy.—Chesley (1944) concludes from the study of several reports that the average total gain during normal pregnancy is 24 lb., with a standard deviation of 45%, or 10.8 lb. Applying this standard to the pooled data he collected from the literature he concluded that two-thirds of all normal patients may be expected to gain between 13 and 35 lb. during the course of pregnancy, and that about one-sixth of all normal patients may be expected to gain more than 35 lb. McIlroy and Rodway (1937) reported that the maximal gain occurred between the 24th and 28th weeks, and many observers aver that a loss of weight may occur during the last two weeks of pregnancy.

Estimates of the amount of nitrogen stored during pregnancy are as high as 1 lb., which would represent more than 6 lb. of protein. If this protein were used in the formation of new tissue it would involve an increase in weight of no less than 30 lb. It may consequently be assumed that the nitrogen, like the sodium, is stored as such, possibly in the liver.

The following figures may be taken as substantially correct and account for most of the increase in weight during pregnancy.

	lb.
(1) The products of conception	11.5
(2) The uterus and adnexa	2.5
(3) Breasts	3.0 ± 1
(4) Increase in the blood volume	2.5

19.5 ± 1

All good milking cows put on considerable amounts of fat during pregnancy, and the same observation is true in man. Fat is usually deposited freely on the hips and round the waist, and the nursing mother can rarely get into tight-fitting frocks which she wore before she became pregnant. This extra fat accounts for another few pounds of weight.

Is any of the additional weight due to excessive water retention? There can be little doubt that the retention of anything up to a litre of water normally occurs

occasioned by a diminution of the salivary secretion, which may be relieved by the injection of pilocarpine, and occasioned by an injection of atropine. The sensation of thirst has, however, been reported in association with excessive salivation (Allison and Critchley, 1943). It must be regarded as a somewhat crude criterion of the degree of hydration of the tissues, and there is often a measurable time lag between the sensation of thirst and a relative degree of dehydration of the tissues. In animal experiments it is not infrequently observed that the dog's tissues are relatively dehydrated although the animal had free access to water. Conversely the animal may drink water greedily immediately it is returned to its cage, shortly after the administration of 250 c.c. of water through the stomach tube.

The small intestine demonstrates a remarkable avidity for water, and absorbs whatever is offered. It was a common custom for German students when *auf die Kniepe* to challenge a companion to drink up to 30 pints of beer within a short period of time. None of this beer was voided through the bowel, it all escaped through the kidneys. What happens to the water after it is absorbed? Klisiecki, Pickford, Rothchild and Verney (1933) concluded, both from their own experiments and from those reported by others, that 250 c.c. of water are absorbed from the small gut of a dog weighing 10 kg. within a period of 36 minutes, that is to say a full 15 minutes before the peak of water diuresis occurs. Further, the peak of water diuresis does not occur until the water load curve has fallen to 76% of its maximum. The water is indubitably absorbed into the blood stream, is offered to the kidneys and refused, and is consequently deposited in the tissue spaces. It does not stay in the blood, for however great be the quantity of water imbibed relatively little dilution of the blood is thereby occasioned.

It is thus clear that the kidneys, the watchdogs of the water exchequer of the body, take from 15 to 30 minutes to make up their minds to open the sluices and let the excess water from the tissues escape. Each human kidney is believed to contain $4\frac{1}{2}$ million glomerulo-tubular units. Assuming that 1 c.mm. of filtrate passed through each glomerulus in an hour, a rate which is known to obtain in the frog, 900 c.c. of urine would be secreted each hour even if 90% of the filtrate were reabsorbed by the tubules. This fact, taken in conjunction with others, led to the view which has been discarded by many modern workers, that the glomerulo-tubular units do not all function at the same time, but enjoy rest pauses. The structure of the kidney certainly makes it possible for blood entering the kidneys to pass direct from the vasa recta into the interlobular capillaries, and thus to by-pass the glomeruli. So far as I am aware the maximum rate of urinary secretion attained by man is in the neighbourhood of 1,200 c.c. an hour, a rate which cannot be long maintained.

Although nervous impulses normally affect the amount of blood supplied to the kidneys, it is beyond dispute that free water diuresis can occur after both kidneys have been completely denervated. The most fascinating and most satisfactory solution of this problem so far advanced, is that minute quantities of the post-pituitary anti-diuretic substance circulating in the blood, cause the tubules to reabsorb most of the water from the glomerular filtrate. It is only when the inhibition occasioned by this substance is temporarily withdrawn that water diuresis can occur.

What are the factors associated with pregnancy which may disturb the normal regulation of the water balance of the body? I shall not discuss the aetiology of the pregnancy toxæmia and their possible association with water retention. The relevant known facts are: (1) A state of hydræmia obtains during pregnancy and is associated with an increase of the blood volume by approximately 20%. (2) The pregnant woman is known to store nitrogen, sodium, iron and other substances. (3) The woman increases in weight during the course of pregnancy. (4) The weight and bulk of the gravid uterus occasion certain mechanical disadvantages which tend to increase until the 38th week of pregnancy.

The increase in the blood volume.—The simplest and most satisfactory explanation of this phenomenon is that it is necessitated by the rapid increase in the size of the vascular bed. The increase of the blood volume results in a compensatory hydræmia. We know that in some forms of anaemia the vascular bed may shrink to approximately half of its normal size, and this device undoubtedly represents nature's effort to make the most of such blood cells as are available, the direct opposite of the course which must be pursued during pregnancy. It would, indeed, be difficult to envisage any other method open to nature to deal with this plumbing emergency.

The hydræmia of pregnancy possibly offers certain advantages. It has been suggested, for example, that the consequent lowering of the blood viscosity facilitates the exchange of oxygen and nourishment through the placental membranes. Whether or not this

be true it is evident that the hydræmic state lessens the number of red blood corpuscles lost during delivery and favours an easy return to the normal blood count when the vascular bed once again returns to its former size.

On the other hand the dilution of the blood lowers the effective osmotic pressure of the plasma colloids and thereby facilitates the escape of fluid from the capillaries to the tissue spaces. This increased loss of fluid from the arterial end of the capillary will clearly cause a correspondingly enhanced concentration of the plasma colloids at the other end of the capillary, and consequently prevent any progressive loss of fluid to the tissues. It is of course important to make sure that the woman's intake of first class proteins is adequate throughout the course of pregnancy, otherwise the effective osmotic pressure of the plasma colloids will fall still further.

The storage of sodium.—It is believed that the increase in the amounts of the sex steroids circulating in the blood is responsible for the storage of nitrogen, sodium and other substances during pregnancy. Heilig (1924) was the first to call attention to a disturbance in the water metabolism at the time of menstruation. Thorn, Nelson and Thorn (1938) found that *œstrone*, progesterone, pregnandiol and testosterone induced retention of sodium chloride and water in normal dogs. They further reported that sodium chloride and water were retained during both the intra- and the pre-menstrual phase of the cycle in man, and that the onset of menstruation was associated with an increased renal excretion of these substances.

If these facts be accepted the difficulty to be faced is not whether the stored sodium could cause water retention but why every pregnant woman does not drown in her own interstitial fluid. The estimates of the amounts of sodium retained during pregnancy vary from 0.23 to 1.26 grammes daily. If it be assumed that this sodium is osmotically active and is held extracellularly it would involve the retention of from 500 to 2,600 c.c. of water each day. Further Hummel *et alia* (1936) found that a nursing mother retained 22 to 27 grammes of sodium in a period of forty-three days. We know, moreover, that the postpartum diuresis occurs while the blood is still hydræmic, and while the excess sodium is still in the tissues. It may therefore be asserted with confidence that neither of these factors, nor both of them acting in concert can be the sole or even the determining factor in causing water retention during pregnancy. The sodium must be stored for the most part in an osmotically inactive form in the tissues.

The increase in weight during the course of pregnancy.—Chesley (1944) concludes from the study of several reports that the average total gain during normal pregnancy is 24 lb., with a standard deviation of 45%, or 10.8 lb. Applying this standard to the pooled data he collected from the literature he concluded that two-thirds of all normal patients may be expected to gain between 13 and 35 lb. during the course of pregnancy, and that about one-sixth of all normal patients may be expected to gain more than 35 lb. McIlroy and Rodway (1937) reported that the maximal gain occurred between the 24th and 28th weeks, and many observers aver that a loss of weight may occur during the last two weeks of pregnancy.

Estimates of the amount of nitrogen stored during pregnancy are as high as 1 lb., which would represent more than 6 lb. of protein. If this protein were used in the formation of new tissue it would involve an increase in weight of no less than 30 lb. It may consequently be assumed that the nitrogen, like the sodium, is stored as such, possibly in the liver.

The following figures may be taken as substantially correct and account for most of the increase in weight during pregnancy.

	lb.

All good milking cows put on considerable amounts of fat during pregnancy, and the same observation is true in man. Fat is usually deposited freely on the hips and round the waist, and the nursing mother can rarely get into tight-fitting frocks which she wore before she became pregnant. This extra fat accounts for another few pounds of weight.

Is any of the additional weight due to excessive water retention? There can be little doubt that the retention of anything up to a litre of water normally occurs

during pregnancy. The legs, arms and face almost invariably increase in size during the course of pregnancy, and a shrinkage in all these three areas is noticeable after delivery and can be correlated with a post-partum water diuresis. The wedding ring must be loose indeed if it does not become tight during pregnancy.

If it may be assumed that an excess of not more than one litre of water may be held in the tissues during the course of normal pregnancy, what would be the maximum amount of water that could be held before visible signs of œdema occurred? I have drunk two litres of water within twenty minutes and this was followed by an unpleasant occipital headache which lasted for several hours, and curiously enough by a metallic taste in the mouth which lasted for more than forty-eight hours. I know of no figures, but should be disposed to doubt whether any woman could hold more than three litres of excess fluid in her tissue spaces without experiencing unpleasant symptoms, and manifesting œdema. These additional two litres would not weigh as much as 5 lb.

Weight gain in relation to the pregnancy toxæmias.—It seems to be an established fact that an abnormal gain in weight frequently precedes the manifestation of toxæmic symptoms. McIlroy and Rodway reported that their 75 toxæmic patients showed a 50% greater increase of weight between the 24th and 38th weeks of pregnancy than their normal patients. Siddall and Mack (1938) found that 61% of their 100 toxæmic patients showed weight gains of at least twice the average at one or more periods after the seventh lunar month, but that the other 39% "had no excessive gain at any time". Indeed, these women gained an average of only 11·6 lb. as compared with 15·7 lb. in normal patients. They also found that 45% of their normal patients showed relatively excessive gains of weight at one or more periods during the last four months of pregnancy.

There has been much confusion of thought with regard to the significance of weight increases in pregnancy. It is beyond dispute that apparently normal women may gain more than 35 lb. during the course of pregnancy. If the weighing of expectant mothers be carried out with a view to detecting the incipient pregnancy toxæmias, and it be assumed that water retention is the incriminating factor, then an increase in weight not exceeding 5 lb. is all that can be anticipated. It follows that a *sudden increase* in weight during the last few weeks of pregnancy may be caused by water retention and be significant. Most available figures suggest that in more than 50% of cases these gains, be they never so sudden, are without significance. The regular weighing of expectant mothers is very important, but provides evidence which is suggestive rather than conclusive.

When does water retention proceed to frank œdema?—œdema can only occur, whether during pregnancy or at any other time, when the permeability of the capillaries is altered either by: (1) malnutrition, (2) chemical poisons or (3) physical injury. Malnutrition may be occasioned by local congestion or represent a local manifestation of the effects of inadequate nutrition. Cohnheim (1909) showed that after long-continued anæmia of the rabbit's ear, the vessels became so permeable that the restoration of the normal circulation was followed by marked œdema of all the tissues. He also found that ligation of the femoral vein in the dog did not cause œdema in a healthy dog, but did if the animal were first rendered anæmic by frequent bleeding. Dr. McMichael authorizes me to say that he has found that if an armlet be applied to the arm of a normal individual, and the pressure in it be raised to 60 mm.Hg, only a limited amount of swelling of the arm will occur below the constriction. The same procedure carried out on a patient suffering from heart failure will result in marked œdema formation. The effects of general malnutrition on the permeability of the capillaries are well exemplified in ankylostomiasis and the wet form of beri-beri. The effects of stagnation on their permeability is evident in cases of heart failure.

The operation of mechanical factors during the course of pregnancy.—I have shown elsewhere (Theobald 1932, 1933) that the bulk of the gravid uterus is liable to elevate and cause a relative fixation of the diaphragm, and thus to raise the intra-thoracic pressure and indirectly increase the general intravenous pressure throughout the body. The weight and bulk of the pregnant uterus cause a more direct and more marked increase of pressure in the veins draining the lower extremities and the lower abdomen, so long as the woman adopts the sitting or the standing position.

Water diuresis (Theobald 1934) curves obtained from normal pregnant women show that they are usually incapable of attaining much more than half the normal rate of urine secretion, neither can they void more than approximately half the amount of water within two and a half hours of its being drunk, so long as they remain either sitting or standing. The intravenous injection of 0·01 unit of post-pituitary extract

nevertheless inhibits water diuresis in these patients, and this fact strongly suggests that the kidneys are willing to excrete the water which is offered to them. It is reasonable to assume that the inadequate water diuresis results from the fact that the water is held in the tissues and is not presented to the kidneys for excretion.

Striking support for this contention is obtained by a very simple experiment (Theobald and Verney, 1935). A normal individual should pass a litre of urine within two and a half hours of drinking that amount of water, and he should reach the peak of diuresis in from 50 to 60 minutes. If he stands absolutely still in the upright position he will not excrete even half the amount of water he imbibes. The probable explanation for this fact is that the absence of muscular contractions in the legs allows the blood to stagnate in the veins, and the water to escape into the tissues. Support for this conjecture is obtained by the simple expedient of bandaging the legs and thighs firmly before the upright position is adopted. The individual will then pass more than 600 c.c. of urine within two and a half hours.

CONCLUSIONS

If we are justified in assuming that an excess of water not exceeding 1 litre may be retained in the tissues during normal pregnancy, and that an additional 2 litres in the tissue spaces is the extreme limit that can be held without causing obvious signs and symptoms, then the additional weight of water in the tissues which precedes the onset of toxæmic symptoms cannot be greater than 5 lb. It is therefore only a sudden, and relatively small increase in weight between the 28th and 38th weeks of pregnancy that can be of suggestive significance.

At least four factors have been regarded as responsible, either in part or in whole, for the excessive water retention which may occur during pregnancy, and they are: (1) The hydræmic state of the blood, and the consequently lowered osmotic pressure of the colloids of the blood plasma, (2) The retention of sodium, (3) The excessive amounts of the sex steroids circulating in the blood, and (4) The mechanical disadvantages occasioned by the size and weight of the gravid uterus. I would stress that *all* of these factors *always* operate during the course of pregnancy, and yet at least 90% of all expectant mothers do not retain a marked excess of water in the tissues. Not one of these factors, nor all of them operating together normally suffice to cause excessive water retention.

The hydræmic state of the blood.—The hydræmia facilitates the transudation of fluid from the blood to the tissues, and lowers the effective osmotic pressure of the plasma colloids. For reasons which I have suggested these two factors could not account for a progressive loss of fluid to the tissues. They might be responsible, at least in part, for the normal excess of fluid in the tissues, and might conduce to the malnutrition of the capillary endothelium. The hydræmia is normal to pregnancy and there is no convincing evidence to show that the blood becomes more diluted in those cases which evince excessive water retention. On the other hand we do know that the blood becomes more concentrated in pre-eclampsia, and in eclampsia itself the red cell count, the hæmoglobin, and the specific gravity of the blood are well above the normal levels. Finally the post-partum water diuresis occurs before any significant change occurs in the direction of blood concentration.

Sodium retention.—Sodium is indubitably retained in considerable amounts, not only during pregnancy, but apparently also during lactation. If this sodium were retained in the tissue spaces in an osmotically attractive form the woman should drown in her own tissue fluids, and unless and until it can be shown that the woman who suffers from œdema also retains more sodium in an osmotically attractive form it is illogical to attribute excessive water retention to sodium. Once again let it be noted that the post-partum water diuresis occurs while the stored sodium is still in the body.

The sex steroids.—No one can be sure of what the sex steroids cannot do. It is generally believed that the amounts of these steroids circulating in the blood tend to fall towards the latter end of pregnancy, just at the time when water retention is likely to occur. No one, so far as I am aware, has shown that they are present in increased amounts in the blood of patients manifesting œdema. The post-partum diuresis certainly accords with the view that the water is in some way held in the tissues by their operation.

The mechanical disadvantages operating during pregnancy.—(a) The healthy pregnant woman cannot give a normal diuretic response to the ingestion of water when in the sitting or standing position. A simple experiment suggests that the increased intravenous pressure results in the stagnation of blood in the large vessels of the lower extremities,

during pregnancy. The legs, arms and face almost invariably increase in size during the course of pregnancy, and a shrinkage in all these three areas is noticeable after delivery and can be correlated with a post-partum water diuresis. The wedding ring must be loose indeed if it does not become tight during pregnancy.

If it may be assumed that an excess of not more than one litre of water may be held in the tissues during the course of normal pregnancy, what would be the maximum amount of water that could be held before visible signs of oedema occurred? I have drunk two litres of water within twenty minutes and this was followed by an unpleasant occipital headache which lasted for several hours, and curiously enough by a metallic taste in the mouth which lasted for more than forty-eight hours. I know of no figures, but should be disposed to doubt whether any woman could hold more than three litres of excess fluid in her tissue spaces without experiencing unpleasant symptoms, and manifesting oedema. These additional two litres would not weigh as much as 5 lb.

Weight gain in relation to the pregnancy toxæmias.—It seems to be an established fact that an abnormal gain in weight frequently precedes the manifestation of toxæmic symptoms. McIlroy and Rodway reported that their 75 toxæmic patients showed a 50% greater increase of weight between the 24th and 38th weeks of pregnancy than their normal patients. Siddall and Mack (1938) found that 61% of their 100 toxæmic patients showed weight gains of at least twice the average at one or more periods after the seventh lunar month, but that the other 39% "had no excessive gain at any time". Indeed, these women gained an average of only 11.6 lb. as compared with 15.7 lb. in normal patients. They also found that 45% of their normal patients showed relatively excessive gains of weight at one or more periods during the last four months of pregnancy.

There has been much confusion of thought with regard to the significance of weight increases in pregnancy. It is beyond dispute that apparently normal women may gain more than 35 lb. during the course of pregnancy. If the weighing of expectant mothers be carried out with a view to detecting the incipient pregnancy toxæmias, and it be assumed that water retention is the incriminating factor, then an increase in weight not exceeding 5 lb. is all that can be anticipated. It follows that a *sudden increase* in weight during the last few weeks of pregnancy may be caused by water retention and be significant. Most available figures suggest that in more than 50% of cases these gains, be they never so sudden, are without significance. The regular weighing of expectant mothers is very important, but provides evidence which is suggestive rather than conclusive.

When does water retention proceed to frank oedema?—Oedema can only occur, whether during pregnancy or at any other time, when the permeability of the capillaries is altered either by: (1) malnutrition, (2) chemical poisons or (3) physical injury. Malnutrition may be occasioned by local congestion or represent a local manifestation of the effects of inadequate nutrition. Cohnheim (1909) showed that after long-continued anaemia of the rabbit's ear, the vessels became so permeable that the restoration of the normal circulation was followed by marked oedema of all the tissues. He also found that ligation of the femoral vein in the dog did not cause oedema in a healthy dog, but did if the animal were first rendered anæmic by frequent bleeding. Dr. McMichael authorizes me to say that he has found that if an armlet be applied to the arm of a normal individual, and the pressure in it be raised to 60 mm.Hg, only a limited amount of swelling of the arm will occur below the constriction. The same procedure carried out on a patient suffering from heart failure will result in marked oedema formation. The effects of general malnutrition on the permeability of the capillaries are well exemplified in ankylostomiasis and the wet form of beri-beri. The effects of stagnation on their permeability is evident in cases of heart failure.

The operation of mechanical factors during the course of pregnancy.—I have shown elsewhere (Theobald 1932, 1933) that the bulk of the gravid uterus is liable to elevate and cause a relative fixation of the diaphragm, and thus to raise the intra-thoracic pressure and indirectly increase the general intravenous pressure throughout the body. The weight and bulk of the pregnant uterus cause a more direct and more marked increase of pressure in the veins draining the lower extremities and the lower abdomen, so long as the woman adopts the sitting or the standing position.

Water diuresis (Theobald 1934) curves obtained from normal pregnant women show that they are usually incapable of attaining much more than half the normal rate of urine secretion, neither can they void more than approximately half the amount of water within two and a half hours of its being drunk, so long as they remain either sitting or standing. The intravenous injection of 0.01 unit of post-pituitary extract

nevertheless inhibits water diuresis in these patients, and this fact strongly suggests that the kidneys are willing to excrete the water which is offered to them. It is reasonable to assume that the inadequate water diuresis results from the fact that the water is held in the tissues and is not presented to the kidneys for excretion.

Striking support for this contention is obtained by a very simple experiment (Theobald and Verney, 1935). A normal individual should pass a litre of urine within two and a half hours of drinking that amount of water, and he should reach the peak of diuresis in from 50 to 60 minutes. If he stands absolutely still in the upright position he will not excrete even half the amount of water he imbibes. The probable explanation for this fact is that the absence of muscular contractions in the legs allows the blood to stagnate in the veins, and the water to escape into the tissues. Support for this conjecture is obtained by the simple expedient of bandaging the legs and thighs firmly before the upright position is adopted. The individual will then pass more than 600 c.c. of urine within two and a half hours.

CONCLUSIONS

If we are justified in assuming that an excess of water not exceeding 1 litre may be retained in the tissues during normal pregnancy, and that an additional 2 litres in the tissue spaces is the extreme limit that can be held without causing obvious signs and symptoms, then the additional weight of water in the tissues which precedes the onset of toxæmic symptoms cannot be greater than 5 lb. It is therefore only a sudden, and relatively small increase in weight between the 28th and 38th weeks of pregnancy that can be of suggestive significance.

At least four factors have been regarded as responsible, either in part or in whole, for the excessive water retention which may occur during pregnancy, and they are: (1) The hydræmic state of the blood, and the consequently lowered osmotic pressure of the colloids of the blood plasma, (2) The retention of sodium, (3) The excessive amounts of the sex steroids circulating in the blood, and (4) The mechanical disadvantages occasioned by the size and weight of the gravid uterus. I would stress that *all* of these factors *always* operate during the course of pregnancy, and yet at least 90% of all expectant mothers do not retain a marked excess of water in the tissues. Not one of these factors, nor all of them operating together normally suffice to cause excessive water retention.

The hydræmic state of the blood.—The hydræmia facilitates the transudation of fluid from the blood to the tissues, and lowers the effective osmotic pressure of the plasma colloids. For reasons which I have suggested these two factors could not account for a progressive loss of fluid to the tissues. They might be responsible, at least in part, for the normal excess of fluid in the tissues, and might conduce to the malnutrition of the capillary endothelium. The hydræmia is normal to pregnancy and there is no convincing evidence to show that the blood becomes more diluted in those cases which evince excessive water retention. On the other hand we do know that the blood becomes more concentrated in pre-eclampsia, and in eclampsia itself the red cell count, the hæmoglobin, and the specific gravity of the blood are well above the normal levels. Finally the post-partum water diuresis occurs before any significant change occurs in the direction of blood concentration.

Sodium retention.—Sodium is indubitably retained in considerable amounts, not only during pregnancy, but apparently also during lactation. If this sodium were retained in the tissue spaces in an osmotically attractive form the woman should drown in her own tissue fluids, and unless and until it can be shown that the woman who suffers from œdema also retains more sodium in an osmotically attractive form it is illogical to attribute excessive water retention to sodium. Once again let it be noted that the post-partum water diuresis occurs while the stored sodium is still in the body.

The sex steroids.—No one can be sure of what the sex steroids cannot do. It is generally believed that the amounts of these steroids circulating in the blood tend to fall towards the latter end of pregnancy, just at the time when water retention is likely to occur. No one, so far as I am aware, has shown that they are present in increased amounts in the blood of patients manifesting œdema. The post-partum diuresis certainly accords with the view that the water is in some way held in the tissues by their operation.

The mechanical disadvantages operating during pregnancy.—(a) The healthy pregnant woman cannot give a normal diuretic response to the ingestion of water when in the sitting or standing position. A simple experiment suggests that the increased intravenous pressure results in the stagnation of blood in the large vessels of the lower extremities,

and the consequent escape of fluid into the tissue spaces. This view obtains some support from the fact that the intravenous injection of minute amounts of post-pituitary extract suffices to inhibit water diuresis in these patients.

(b) The expectant mother tends to pass more urine by night than by day.

(c) Rest in bed cures most cases of pregnancy œdema, unless the condition is associated with gross malnutrition. It is not the rest, I suggest, but the horizontal position which effects the cure, and exercise in bed could but aid the process.

(d) Ankylostomiasis is not usually associated with œdema, but up to 90% of all gravid women who are heavily infected with this parasite show not only œdema, but also anasarca.

(e) Water retention is more common in association with primiparity and multiple pregnancy.

(f) Water diuresis occurs shortly after delivery when the blood is still hydræmic and the sodium is still retained. Unless it can be shown that the sex steroids directly cause the retention of water in the tissue spaces, this one fact almost proves that mechanical factors are those which actually determine the water retention of pregnancy.

Once the excess water stored in the tissues by day ceases to escape by night, abnormal retention can proceed at an alarming pace. The slightest alteration in the permeability of the capillary endothelium, whether caused by malnutrition due to venous stagnation, or to general malnutrition, might result in a very rapidly extending œdema, and the œdema fluid might contain considerable amounts of protein. It is only necessary to call to mind the heavy albuminuria which may be occasioned in susceptible subjects by the sudden adoption of the upright position, to realize the catastrophic effects which might result from small changes in the permeability of the capillary endothelium. The constant wonder to me is that pregnancy is ever normal.

I would suggest that a well-balanced, easily digested, and attractive diet, containing plenty of first-class proteins, and adequate amounts of the vitamins and necessary minerals; plenty of exercise, well-emptied bowels, and a healthy mind are the best means of preventing excessive water retention. Theoretically it is important to limit the intake of table salt and sodium bicarbonate, and although many authorities consider this important I have never found it necessary. The water balance may be restored in three different ways; by limiting the intake of water, by diuretics, and by increasing the period of "rest" on the back.

Mr. W. C. W. Nixon: *Water metabolism in pregnancy*.—œdema in pregnancy is one of the main clinical manifestations of abnormal water metabolism. The type of œdema seen in non-toxæmic women has not received enough attention. In Hong Kong, in the year 1936 (Nixon 1938) the incidence of œdema was 16.3% of admissions to the University Obstetric Clinic. Of these 210 cases (9.3%) had œdema, without toxæmia, lasting more than seven days at some time or other during pregnancy. Only those women who had a systolic blood-pressure below 130 mm.Hg. and were free from albuminuria were included in the investigation. Certain conclusions were reached. There was no significant difference between: (1) The duration of œdema and parity; (2) the systolic blood-pressures of primigravidae and multigravidae; (3) the average blood-pressure of the œdematous group and the non-œdematous control group; and (4) the onset of œdema was not associated with a rise in blood-pressure.

On my return to this country in company with Drs. Wright and Fieller (1942) a small group of cases (14) of non-toxæmic pregnancy œdema were investigated for vitamin B₁ deficiency. We did not find any significant difference in the vitamin B₁ excretion between this group and the controls. Apart from toxæmia the most

impressive clinical example of abnormal water retention is to be seen in pregnancy complicated by beri-beri. Professor Gordon King's (1941) report on the work in the Hong Kong University Obstetric Clinic is of particular interest. The following table is taken from this report and shows the deaths due to beri-beri.

DEATHS FROM BERI-BERI IN PREGNANCY

(Hong Kong University, 1940)						
Pyruvic acid	Age	Gravida	Maturity	Œdema	Duration	Onset
—	20	1	?	Legs	5½ months	—
—	24	2	38	Legs	1½ months	—
—	25	1	40	Legs	1 month	—
—	28	1	36	Extremities	—	—
—	—	—	—	Abdominal wall	3 months	—
1.45	24	2	40	Legs	1½ months	—
—	22	1	38	Abdom., legs	1½ months	—
—	27	2	38	Legs	3 weeks	—
2.70	40	9	39	Legs	2 months	—
2.40	28	4	43	Legs	1½ months	—
0.96	36	5	35	Legs	2 months	—
0.93	25	1	39	Legs	—	—
0.85	28	4	40	Legs	4 months	—
0.80	21	1	?	General	3 months	—
0.60	22	1	33	Legs	2 months	25th week
1.10	36	5	40	Legs	1 month	—
0.49	23	5	32	Legs	1½ months	26th week
—	34	9	29	Legs	1 month	25th week

I have analysed this table in an attempt to demonstrate the super-added strain of pregnancy in a malnutrition state. It is in consideration of these deaths that an important fact emerges, namely, the duration of œdema. The maximum duration was five and a half months and the minimum three weeks; in most women it was for one or two months. Three of the deaths were as early as the 29th, 32nd and 33rd week respectively and what is interesting in these is that the œdema was first noticed at an early stage, namely, the 25th, 26th and 25th week respectively. These cases showed the strain of pregnancy early and with this death took place at an earlier date than in the rest of the group.

Professor King has extended this study of œdema and has classified such cases into three groups (a) those associated with pregnancy toxæmia, (b) those associated with avitaminosis B₁, (c) those not accompanied by signs of either pregnancy toxæmia or avitaminosis B₁. The paper he and Professor Ride (1945) published in which they reviewed 371 cases of beri-beri complicating pregnancy merits careful study. They advanced arguments to support the view that a causal relation exists between a deficiency of vitamin B₁ and the occurrence of pregnancy toxæmia. I will quote their concluding paragraph: "Prophylaxis and/or active treatment by the exhibition of adequate amounts of vitamin B₁ whether in the form of a vitamin-rich diet or as thiamine medication, is suggested as perhaps the most important single measure dealing with pregnancy toxæmia in any of its forms."

An extensive literature has accumulated concerning water balance in pregnancy. Arnell and Guerriero (1942) have investigated a group of 500 pregnant women who presented varying degrees of œdema. Some could be explained as cardiac, renal, toxæmic in origin, others as inflammatory or mechanical—thrombophlebitis, angio-neurotic œdema, varicose veins. Other predisposing factors were hot weather, dependent position, excessive ingestion of salt and water. But there was one very interesting group in which hypoproteinæmia and anæmia were present. I would suggest that in those cases where there is œdema of the vulva without hypertension or albuminuria the serum protein should be estimated. I take for granted that the Hb of every expectant mother is examined as a routine. Dexter and Weiss (1941) found unequivocal signs of œdema of the face or hands or both between 32nd week and term in 64% of a hundred consecutive normal pregnant women. In 7% of the normal pregnant women with generalized œdema, symptoms such as frontal headaches, visual disturbances, nausea and vomiting—similar to the symptoms in pregnancy toxæmia or in severe premenstrual œdema—were noted. There was a close relation between the cerebral symptoms and the daily appearance of facial œdema.

I am relieved that even these authorities find that the mechanism of œdema of normal pregnancy, like that of pre-eclampsia and eclampsia, cannot be explained by any of the usual causes for œdema formation. By exclusion, they suspect a chemical or hormonal aetiology resulting in retention of water and electrolytes in the tissues. Of course, towards the end of pregnancy there is a physiological hydræmia with consequent reduction in protein, hæmoglobin and other blood constituents. But this will not explain the œdema that sometimes develops in normal pregnancy before the last

trimester. The clinical manifestations of excessive menstrual œdema, excessive œdema of normal pregnancy and excessive œdema of mild, pre-eclamptic toxæmia are frequently quite similar.

Site of œdema.—The feet and hands are common places for œdema and the explanation is probably postural. The vulva I have already mentioned and the need to estimate serum proteins when this region is involved. The face and eyes are influenced by gravity; here the œdema is worse in the morning after recumbency. With assumption of the upright position œdema of the face subsides and ankle œdema becomes more noticeable. I find that examination of the conjunctiva is often neglected; there will be found the tears that do not run. By pressing on the lower eyelid the subconjunctival œdema can be easily seen.

Treatment.—In prophylaxis the two most important items are dietetic, namely, a high protein but a salt-free diet. Every pregnant woman should have at least 100 grammes or more of protein daily and most of this should be first-class. Unfortunately there are still antenatal clinics where women are put on a protein-free diet for weeks on end because they exhibit either a slight hypertension, albuminuria or œdema. Nothing but harm can result from this. Strauss (1935) has conclusively shown the beneficial effect of protein in pregnancy toxæmia. We should insist more firmly on a salt-free diet during pregnancy. de Snoo (1937) has claimed that without sodium chloride retention there is no eclampsia. All indigestion powders and mixtures containing sodium should be vetoed. Likewise the diabolical habit that women in this country have of cooking vegetables with soda is to be condemned. By this practice not only do they destroy all the vitamin C but expose themselves to the risk of water retention.

Slight œdema will sometimes disappear when alkalis are given. Green-Armytage (1936) has treated cases of transient œdema successfully with daily doses of $\frac{1}{4}$ or $\frac{1}{2}$ oz. of bicarbonate of soda and potassium citrate. Again I would emphasize that potassium and not sodium salts should be used. Diuretics such as potassium or ammonium chloride can also be used. Mercurial diuretics in my experience are contra-indicated as I have known them to induce albuminuria.

Moderate or excessive œdema needs more energetic treatment. Bed is essential. By eliminating the effect of dependency and physical exercise improvement will follow. A fluid intake and urine output chart is of paramount importance. It is a mistake to flood a "waterlogged" patient with fluid, particularly intravenous saline, as is still being practised. For the first twenty-four hours I restrict the fluid intake to 500 c.c. of 30% glucose and increase the intake to 50 c.c. less than the previous day's output. The caloric value of the diet should be between 1,200 to 1,500 and consist mainly of sugar, skimmed milk, vegetables and fruit (if available).

Intravenous glucose (50 to 100 c.c. of 50% solution 6-hourly) is recommended until diuresis has been established. When glucose is being given vitamin B₁ is especially indicated. This vitamin is necessary for the oxidation of intermediate metabolites—pyruvic acid—in carbohydrate metabolism. In its absence there is incomplete combustion of carbohydrate. This is what happens in beri-beri.

Whenever diuresis is being induced the body suffers from vitamin depletion. Dr. Frederick Prescott of the Wellcome Foundation suggests that during the period of diuresis vitamins should be given daily in the following amounts: Vitamin B₁ 10 mg.; vitamin C 300 mg.; nicotinic acid 100 mg.; riboflavin 5 mg.

Vitamin C in large doses is known to have a diuretic effect and nicotinic acid has a strong vasodilator action. Recently malarial headache has been relieved by nicotinic acid (100 mg.). These headaches are due to slowing of rate of cerebral blood with resultant venous congestion, focal cerebral œdema and anoxia. I suggest that there may be a place for the use of this vitamin in pregnancy toxæmia. It relieves arteriolar spasm.

Finally, there is a place for plasma transfusion if hypoproteinæmia is an ætiological factor. A plasma transfusion of 500 c.c. is equivalent to 40 grammes of protein.

The Problem of "Postmaturity"

By A. J. WRIGLEY

THE problem of "postmaturity" is not new. F. J. Browne (Ballantyne and Browne, 1922) says the problem is as old as the hills and has been noted in many ancient civilizations.

Unfortunately most of us assume that if any pregnancy continues over the calculated date for its termination, the fetus will become so large as to give rise to difficulty in its delivery. That this is not the case has long been recognized.

In 1902 Ballantyne noted that a baby weighing more than the usual number of pounds may be born at the normal time. Twenty years later he and Browne wrote: "There is no proof that if the weight of the postmature baby is near the average (as it sometimes is) the labour will be more dangerous than usual." And in 1938 Neon Reynolds told us that: "Postmaturity has peculiar difficulties as a subject for discussion, since we have at present no definition of what we mean. . . . Foetal development, well above the average as regards size, weight, ossification, &c., is not necessarily a result of prolonged gestation, just as immaturity is not synonymous with prematurity."

Adair (1940) writes: "There are individuals who persistently delay in the normal onset of labour, each pregnancy being of a longer duration than the average normal, the fetal size appearing to have no bearing on this phenomenon. The fetus may be over-size, of normal or below normal weight."

In the year 1945 there occurred some thousand deliveries in the St. Thomas's Obstetric Unit. The following tables well illustrate my point.

We first collected all those cases of women who were delivered of a baby weighing 9 lb. or over (Table I).

TABLE I.

No. of cases	Weight of babies		Estimated maturity in days \pm			
	lb. oz.	lb. oz.				
9	9 0	9 3	+18, +16 + 8, + 4 + 4	-2, -4, 0	-3 -20	
5	9 4	9 7	+40, +13 + 5	-8,	-5	
6	9 8	9 11	+ 6, + 4 + 4, + 3 + 1	0		
6	9 12	9 15	+13, +12 + 7, + 6	-2,	-3	
3	10 8		+16, +12	-5		
1	10 13			0		
1	12 0		+24			

We next estimated the weight of the babies delivered more than seven days after the calculated date (Table II).

TABLE II—BABIES' WEIGHT.

No. of cases	No. of weeks "postmature"	No. at birth weighing:					
		5 lb.	6 lb.	7 lb.	8 lb.	9 lb.	Over 9 lb.
16	1	0	5(1)*	3	5	3	0
43	2	2	6	10	11(1)*	5	0
18	3	1	7	6	2	1	0
8	4	1	2	3	2	0	0
4	5	0	2	0	2	0	0
Total 89							

*Stillbirth

Note how frequently a large healthy baby is born before the calculated date and secondly, how often a small baby, or one of normal weight, is born after the expected date. I must add that all these women had been observed throughout their pregnancies, and the expected date was calculated not only from the date of the last menstrual period but was correlated with the time of the onset of quickening and with regular observations in the rate of enlargement of the uterus.

Similar advice can be found in a few textbooks. In the Queen Charlotte's Textbook of Obstetrics (1939) we read: "There is no exact time for gestation. An apparently full-time child born 207 days after marriage has been held by law to be the legitimate off-spring of its parents. A child born 331 days after its mother's husband had left the country was held to be legitimate." Berkeley, Bonney and MacLeod (1938) in "The Abnormal in Obstetrics" mention a child "undoubtedly 6 weeks postmature" which weighed less than 5 lb. at birth. R. W. Johnstone (1937) in his Textbook of Midwifery writes: "That pregnancy followed by the birth of a fully developed child may be prolonged or

abbreviated is an observed fact. The usual explanation is a miscalculation as to dates." Fairbairn (1928) stated that: "In many cases of prolonged gestation the foetus is only of average development, and many cases of postmaturity are not accompanied by increase in the duration of pregnancy." From America, Henricus Stander in Williams' *Obstetrics* (1936) advises us that: "In the majority of cases of supposed prolongation, the delay is only apparent and the child does not greatly exceed the average."

The above extracts were collected from a search in the current textbooks of obstetrics. In most of the remainder, and they constitute the great majority, either the subject is ignored or the reader led to believe in the words of the Ten Teachers (1938) that the best evidence of a real prolongation of the period of utero-gestation is an abnormal length and weight of the infant. Likewise Munro Kerr (1937) states that: "In protracted gestation, without doubt, the child frequently suffers, and even dies", and lastly Berkeley (1938) wrote: "The average duration of pregnancy being estimated as 280 days from the first day of the last period, if the pregnancy is prolonged 10 days over such a calculation the child may be deemed to be postmature. In such cases the child is always above the average length and, most frequently, above the average weight. The head is larger and harder than normal, giving rise to difficult labour, during which the child may perish." This last is indeed a grave warning.

I maintain that we have consistently ignored the advice given us in the first series of quotations and have based our definition of postmaturity on the lines of the last three extracts, viz. that a baby born after the expected time will be large, that a baby born before the expected time will be small and that a baby born at the expected time will be "normal" in weight.

Certainly we have educated the laity on these lines. The fact that the baby has not come on the expected date is almost always likely to create a sense of anxiety which increases as one day (or week) follows another. Anyone who questions a student at the final examinations on this subject cannot fail to acknowledge that either the student has never heard the problem discussed at all, or, should he or she have been educated at one of two London Medical Schools, the answer given is to the effect that when fourteen days have elapsed labour should be induced. This reply is as fatuous as it is dangerous.

I will now turn to the question of the Diagnosis of Postmaturity.

Brown, in "Antenatal and Postnatal Care" (1944), and in the paper of 1922 already referred to, discussed the following points:—

(1) A careful scrutiny of menstruation with special reference to women who constantly miss one or more periods.

(2) Valuable evidence from the date of quickening.

(3) The foetal head; its size, its hardness, the mobility of the skull bones, the width of the sutures and fontanelles, may be estimated with a fair approach to accuracy by the examining finger in the vaginal fornices or by palpating the head through the open cervix.

(4) Foetal mensuration: "No method is sufficiently accurate to be of use in clinical practice."

(5) Cephalometry by X-rays: "It is possible by measuring the size of the foetal skull by means of X-rays to arrive at a more or less accurate estimate of the size and weight of the foetus."

This table is accepted for the most part by other authors such as Masters and Clayton (1940), Reynolds, the Ten Teachers and Cameron (1939).

As variants Jellett (1930), Comyns Berkeley and Titus in America (1940), suggest that the diagnosis is made on the fit of the foetal head into the pelvic brim. Jellett and Madill (1929) advise "the length of the foetal ovoid can be directly measured by placing one blade of the calipers on the pelvic pole of the foetus *per vaginam*, and the other blade on the abdominal wall in close contact with the fundal pole".

Herman (1939) and Henricus Stander deny that the foetal head is likely to be of much help in the making of the diagnosis, and the former points out a fact of considerable clinical importance when he adds that in the case of large babies, whose intra-uterine development is excessive, the shoulders are larger in comparison with the head than is normal and with such a child the excessive size of the shoulders may greatly obstruct delivery. Fairbairn advised that it virtually was not possible to make the diagnosis of postmaturity during pregnancy as there was no accurate method of determining the size of the foetus. Berkeley and Bonney seem to agree with this and suggest the diagnosis usually is suspected during an obstructed labour and confirmed when the baby has arrived. I was unable to discover any mention of the diagnosis in the books written by Bourne (1941), Gibberd (1938), Johnstone, Munro Kerr or in the Queen Charlotte's Textbook.

From the above evidence the question will now be criticized collectively, and, according to the symptoms and signs, individually. Collectively you must agree the outlook is discouraging. The advice is contradictory or absent. Individually each symptom or sign fails to be absolute, and by itself never more than suggestive. The reason for these facts surely rests on exactly the same faults as we saw applied to the difficulties that arose on the question of the definition of the condition. Nearly every author has written on the assumption that postmaturity must be the synonym for what Herman termed excessive intra-uterine development of the foetus, and yet most of them knew that this was not the case.

Lastly in this respect I would refer to the failure of radiography to help in the diagnosis.

Browne writes: X-rays are of little help, though the existence of a very large ossific centre in the cuboid would be confirmatory evidence of postmaturity"; but the following sentence reads: "The ossific centre may, however, be of this size without the foetus being postmature(!)." Gibberd agrees and believes that "there is such wide variation in the times of appearance of the ossific centres that they are of little use in this connexion". Reece (1935) suggested that the maturity of the foetus could be calculated almost to the day by means of foetal cephalometry. He was answered by Reynolds in the words: "It is difficult to believe that any diameter is such a fixed factor that it is possible to say, because the diameter is 3.75 inches that therefore the foetus is of 40 weeks' maturity". Are we all then made alike?

Munro Kerr stating that he does not feel sufficiently experienced to pronounce judgment on foetal cephalometry most rightly proceeds: "I would, however, say this, that it will never be possible to estimate mouldability of the head, minor adjustments of the head to the pelvis, and the power of the expulsive forces, which are of primary importance in determining whether the head will or will not pass through a pelvis."

I would value Fairbairn's advice as the most valuable but he omitted to give us the reason for his statement, which should have been followed by a sentence to the effect that a postmature baby need not be unduly large and a premature baby is not, of necessity, unduly small.

Treatment or management.—This makes even more depressing reading and again I must quote freely.

In the first place I was unable to discover any advice on the management of women who have passed the expected date of confinement in the books written by Fairbairn, Gibberd, Jellett and Madill, Johnstone or the Ten Teachers. In Berkeley's "Handbook of Midwifery" appears the sentence: "Cases of suspected postmaturity are treated by Induction of Labour." The reader has been given no hint previously how postmaturity may be "suspected". In "Difficulties and Emergencies of Obstetric Practice" (Berkeley and Bonney), I read: "When a practitioner is satisfied that pregnancy has progressed beyond its normal limits he should induce labour." This is preceded by a statement that: "The abnormal size of the child is discovered during labour"! and no guidance is given to the practitioner to provide him with that satisfaction that the pregnancy has progressed beyond its normal limits. Cameron writes: "As there is no possible advantage to either mother or child, labour should be induced when it is reasonably certain that the pregnancy has run its full course." Again the whole sentence hangs on the word "when?". Lastly, exactly the same criticism applies to Munro Kerr, who in the Combined Text Book states: "Where there is good reason to think that a pregnancy has definitely exceeded the normal duration, the induction of labour should be seriously considered." We receive no help either in this book as to "Where there is good reason". So far, then, so bad.

Several authorities are more definite on their advice as to when induction should be performed. Browne says: "While, however, it would be strictly speaking, correct to term a woman postmature if she has gone more than eight days past her expected date, it would be absurd to class her as abnormal, and therefore needing treatment. She could only be considered abnormal if she were exceptional and it is certainly not abnormal for a woman to go eight days past her estimated date of delivery. A good clinical rule is that she should not be allowed to go more than a fortnight past her estimated date, always provided that these dates have been correctly ascertained." My criticism of the above is that the reader would certainly interpret the advice as never induce at the eighth day and always by the fifteenth day after the expected date (correctly ascertained). This interpretation is fraught with danger, for the baby may easily be more truly postmature on the eighth day than it is on the fifteenth, and I venture to agree with Browne himself that "dates" are more notoriously misleading. Queen Charlotte's Textbook repeats Browne's advice with: "Labour should be generally induced whenever a patient is more than a fortnight overdue." Nothing else is said and can the student be blamed if he regards this as dogma?

Berthel Solomons advises induction at the 40th week provided that "it is certain that the date is correct (it never is certain) and if the head just fits the brim". The foetal head may be deep in the pelvis and yet the foetus be grossly postmature and of a dangerously large size.

Munro Kerr in "Operative Obstetrics" likewise discusses the fit of the foetal head and advises what may be termed "A Test Induction". This is a full medical induction which "seldom brings on labour unless gestation has reached full term, but almost certainly does so if it has". I deny the accuracy of this statement and will refer to possible unfortunate results of this treatment later in the paper. Jellett's treatment is contained in the words: "The expulsion of the foetus is left to the natural efforts as long as possible."

Masters and Clayton are definitely against a routine induction of labour. "It would seem unjustifiable to induce labour in patients who are thought to be postmature, but in which there is no evidence of disproportion for the following reasons: (1) The un-

abbreviated is an observed fact. The usual explanation is a miscalculation as to dates." Fairbairn (1928) stated that: "In many cases of prolonged gestation the foetus is only of average development, and many cases of postmaturity are not accompanied by increase in the duration of pregnancy." From America, Henricus Stander in Williams' *Obstetrics* (1936) advises us that: "In the majority of cases of supposed prolongation, the delay is only apparent and the child does not greatly exceed the average."

The above extracts were collected from a search in the current textbooks of obstetrics. In most of the remainder, and they constitute the great majority, either the subject is ignored or the reader led to believe in the words of the Ten Teachers (1938) that the best evidence of a real prolongation of the period of utero-gestation is an abnormal length and weight of the infant. Likewise Munro Kerr (1937) states that: "In protracted gestation, without doubt, the child frequently suffers, and even dies", and lastly Berkeley (1938) wrote: "The average duration of pregnancy being estimated as 280 days from the first day of the last period, if the pregnancy is prolonged 10 days over such a calculation the child may be deemed to be postmature. In such cases the child is always above the average length and, most frequently, above the average weight. The head is larger and harder than normal, giving rise to difficult labour, during which the child may perish." This last is indeed a grave warning.

I maintain that we have consistently ignored the advice given us in the first series of quotations and have based our definition of postmaturity on the lines of the last three extracts, viz. that a baby born after the expected time will be large, that a baby born before the expected time will be small and that a baby born at the expected time will be "normal" in weight.

Certainly we have educated the laity on these lines. The fact that the baby has not come on the expected date is almost always likely to create a sense of anxiety which increases as one day (or week) follows another. Anyone who questions a student at the final examinations on this subject cannot fail to acknowledge that either the student has never heard the problem discussed at all, or, should he or she have been educated at one of two London Medical Schools, the answer given is to the effect that when fourteen days have elapsed labour should be induced. This reply is as fatuous as it is dangerous.

I will now turn to the question of the Diagnosis of Postmaturity.

Brown, in "Antenatal and Postnatal Care" (1944), and in the paper of 1922 already referred to, discussed the following points:—

(1) A careful scrutiny of menstruation with special reference to women who constantly miss one or more periods.

(2) Valuable evidence from the date of quickening.

(3) The foetal head; its size, its hardness, the mobility of the skull bones, the width of the sutures and fontanelles, may be estimated with a fair approach to accuracy by the examining finger in the vaginal fornices or by palpating the head through the open cervix.

(4) Foetal mensuration: "No method is sufficiently accurate to be of use in clinical practice."

(5) Cephalometry by X-rays: "It is possible by measuring the size of the foetal skull by means of X-rays to arrive at a more or less accurate estimate of the size and weight of the foetus."

This table is accepted for the most part by other authors such as Masters and Clayton (1940), Reynolds, the Ten Teachers and Cameron (1939).

As variants Jellett (1930), Comyns Berkeley and Titus in America (1940), suggest that the diagnosis is made on the fit of the foetal head into the pelvic brim. Jellett and Madill (1929) advise "the length of the foetal ovoid can be directly measured by placing one blade of the calipers on the pelvic pole of the foetus *per vaginam*, and the other blade on the abdominal wall in close contact with the fundal pole".

Herman (1939) and Henricus Stander deny that the foetal head is likely to be of much help in the making of the diagnosis, and the former points out a fact of considerable clinical importance when he adds that in the case of large babies, whose intra-uterine development is excessive, the shoulders are larger in comparison with the head than is normal and with such a child the excessive size of the shoulders may greatly obstruct delivery. Fairbairn advised that it virtually was not possible to make the diagnosis of postmaturity during pregnancy as there was no accurate method of determining the size of the foetus. Berkeley and Bonney seem to agree with this and suggest the diagnosis usually is suspected during an obstructed labour and confirmed when the baby has arrived. I was unable to discover any mention of the diagnosis in the books written by Bourne (1941), Gibberd (1938), Johnstone, Munro Kerr or in the *Queen Charlotte's Textbook*.

From the above evidence the question will now be criticized collectively, and, according to the symptoms and signs, individually. Collectively you must agree the outlook is discouraging. The advice is contradictory or absent. Individually each symptom or sign fails to be absolute, and by itself never more than suggestive. The reason for these facts surely rests on exactly the same faults as we saw applied to the difficulties that arose on the question of the definition of the condition. Nearly every author has written on the assumption that postmaturity must be the synonym for what Herman termed excessive intra-uterine development of the foetus, and yet most of them knew that this was not the case.

Lastly in this respect I would refer to the failure of radiography to help in the diagnosis.

Browne writes: X-rays are of little help, though the existence of a very large ossific centre in the cuboid would be confirmatory evidence of postmaturity"; but the following sentence reads: "The ossific centre may, however, be of this size without the foetus being postmature(!)." Gibberd agrees and believes that "there is such wide variation in the times of appearance of the ossific centres that they are of little use in this connexion". Reece (1935) suggested that the maturity of the foetus could be calculated almost to the day by means of foetal cephalometry. He was answered by Reynolds in the words: "It is difficult to believe that any diameter is such a fixed factor that it is possible to say, because the diameter is 3.75 inches that therefore the foetus is of 40 weeks' maturity". Are we all then made alike?

Munro Kerr stating that he does not feel sufficiently experienced to pronounce judgment on foetal cephalometry most rightly proceeds: "I would, however, say this, that it will never be possible to estimate mouldability of the head, minor adjustments of the head to the pelvis, and the power of the expulsive forces, which are of primary importance in determining whether the head will or will not pass through a pelvis."

I would value Fairbairn's advice as the most valuable but he omitted to give us the reason for his statement, which should have been followed by a sentence to the effect that a postmature baby need not be unduly large and a premature baby is not, of necessity, unduly small.

Treatment or management.—This makes even more depressing reading and again I must quote freely.

In the first place I was unable to discover any advice on the management of women who have passed the expected date of confinement in the books written by Fairbairn, Gibberd, Jellett and Madill, Johnstone or the Ten Teachers. This reply is as fatuous as it is dangerous.

I will now turn to the question of the Diagnosis of Postmaturity.

Browne, in "Antenatal and Postnatal Care" (1944), and in the paper of 1922 already referred to, discussed the following points:—

(1) A careful scrutiny of menstruation with special reference to women who constantly miss one or more periods.

(2) Valuable evidence from the date of quickening.

(3) The foetal head; its size, its hardness, the mobility of the skull bones, the width of the sutures and fontanelles, may be estimated with a fair approach to accuracy by the examining finger in the vaginal fornices or by palpating the head through the open cervix.

(4) Foetal mensuration: "No method is sufficiently accurate to be of use in clinical practice."

(5) Cephalometry by X-rays: "It is possible by measuring the size of the foetal skull by means of X-rays to arrive at a more or less accurate estimate of the size and weight of the foetus."

This table is accepted for the most part by other authors such as Masters and Clayton (1940), Reynolds, the Ten Teachers and Cameron (1939).

As variants Jellett (1930), Comyns Berkeley and Titus in America (1940), suggest that the diagnosis is made on the fit of the foetal head into the pelvic brim. Jellett and Madill (1929) advise "the length of the foetal ovoid can be directly measured by placing one blade of the calipers on the pelvic pole of the foetus *per vaginam*, and the other blade on the abdominal wall in close contact with the fundal pole".

Herman (1939) and Henricus Stander deny that the foetal head is likely to be of much help in the making of the diagnosis, and the former points out a fact of considerable clinical importance when he adds that in the case of large babies, whose intra-uterine development is excessive, the shoulders are larger in comparison with the head than is normal and with such a child the excessive size of the shoulders may greatly obstruct delivery. Fairbairn advised that it virtually was not possible to make the diagnosis of postmaturity during pregnancy as there was no accurate method of determining the size of the foetus. Berkeley and Bonney seem to agree with this and suggest the diagnosis usually is suspected during an obstructed labour and confirmed when the baby has arrived. I was unable to discover any mention of the diagnosis in the books written by Bourne (1941), Gibberd (1938), Johnstone, Munro Kerr or in the Queen Charlotte's Textbook.

From the above evidence the question will now be criticized collectively, and, according to the symptoms and signs, individually. Collectively you must agree the outlook is discouraging. The advice is contradictory or absent. Individually each symptom or sign fails to be absolute, and by itself never more than suggestive. The reason for these facts surely rests on exactly the same faults as we saw applied to the difficulties that arose on the question of the definition of the condition. Nearly every author has written on the assumption that postmaturity must be the synonym for what Herman termed excessive intra-uterine development of the foetus, and yet most of them knew that this was not the case.

Lastly in this respect I would refer to the failure of radiography to help in the diagnosis.

observer has been watching the particular patient at regular intervals throughout her pregnancy and at frequent intervals throughout the later weeks. For instance, whereas the amount of liquor amnii varies considerably in different women, in all women there should be a relative, and as full time is reached, a noticeable apparent decrease in amount. Emphasis is laid on this last sentence. As an example could be cited the multipara who as a result of many pregnancies has a poor abdominal musculature, a lax toneless uterine wall and very often a tendency to slight hydramnios. The casual observer, seeing this patient at the estimated 42nd week of pregnancy, could not possibly be expected to say that the uterus contains "a more easily palpated foetus" or "an apparently decreased amount of liquor". If, however, this patient has been observed regularly by the same person, both these findings, which it is held, are of considerable importance, may be recorded with confidence. No other physical sign, or symptom, is put forward for consideration. It is contended that all the remainder are not only of little use but may actually be misleading.

At this point a plea is made for a complete revision of many of our ideas on pregnancy and its termination. At the present time each patient is given an "expected date". This date is necessary, because probably it will be fairly accurate, and because many and various arrangements have to be made for the forthcoming confinement. But at the same time let us be more careful always to explain to our patients that, at the best, the date may be only approximate and that the baby may arrive before or after, perhaps considerably after the expected time. Also let us say at once that it will probably never be possible at any time during the pregnancy to make a more accurate forecast.

On or about the "calculated date" it is expected that the woman will start her labour and produce a healthy baby weighing about 7 lb. These two events do in fact take place in the majority of patients. But in quite a considerable minority variations occur. These variations are three in number and as each one is of the greatest importance they deserve emphasis.

First, the expected date may come and go and the labour start some days or weeks later with the delivery of a large postmature baby. Secondly, the expected date may come and go and the labour start some days or weeks later with the delivery of a normal-sized baby (that is to say, about 7 lb. in weight and 20 in. in length) or even of a baby that is even less in both weight and length. Thirdly and lastly, at or about the time of the calculated expected date, or even earlier, the labour starts and the woman is delivered of a large, oversized baby that shows every characteristic attributed to postmaturity.

Now, as I have already stated, it is accepted by the laity, and by the great majority of the medical profession that a baby born before the expected date will be smaller than the normal, that a baby born at the expected date will be of normal dimensions and that a baby born after the expected date will be larger than the normal. Such is usually, but by no means always, the case. The Irish members of the audience will appreciate what is meant, when it is stated that a postmature baby may well be born prematurely and a premature baby may arrive after the calculated 40 weeks have come and gone.

A lack of appreciation of these facts results in a great deal of anxiety on the part of the lay public and of their medical attendants and as a result leads also to a deal of bad midwifery. Thus it is just as important to try to realize that when the expected date of confinement has been passed, the foetus may not necessarily be mature as it is to realize that it may be, and perhaps dangerously so, postmature.

Attention has already been drawn to the difficulties in diagnosis and to the absence of, or at the best, the most indefinite assistance given on this subject in the current textbooks of obstetrics. Because of this the medical attendant adopts one of two courses. Either every woman who passes the calculated date of confinement receives a medical induction, or, in the realization that many "postmature" babies are not unduly large, the rule of "leave it to Nature" is adopted with the result that occasionally the wretched patient delivers herself of a large truly postmature baby, perhaps with great difficulty and considerable risk to herself and to the baby. Both courses are equally reprehensible. Furthermore there is no justification whatever for advising that a week or a fortnight should be allowed to elapse after the expected date has passed and at that time if labour has not started the labour should be induced. If this advice is followed, in the first place a number of women will go into labour later than they should be allowed to do and true postmaturity be ignored, or alternatively the baby may well, even at the calculated 42nd week, not be mature.

Another great objection to this plan is that all too often it leads to repeated medical inductions. Apart from the inevitable physical upheaval of such proceedings which

certainly of any diagnosis of postmaturity; (2) the lack of any definite evidence that placental degeneration causes foetal death; (3) the risk of inertia." While I would be prepared to agree with this advice, much more constructive help can be given.

In three American textbooks, however, we find much more encouragement. Titus, after a short summary on the assessment of a large foetus in which he draws attention to the size of the abdomen, the size and hardness of the foetal head and the danger of the large shoulder girdle, advises that: "When it can be demonstrated that the fetus is large and the available evidence indicates that labour is overdue, its induction is indicated." Stander writes: "If the patient has gone beyond term and the examination shows that the size of the child is above average, there should be no hesitancy in the induction of labour as a prophylactic measure. On the other hand, if the child is small, induction should not be thought of. Excessive size of the child is rarely suspected by the ordinary practitioner before the onset of labour and the diagnosis is only made after Nature has shown that she is unable to effect delivery. If the patient is carefully palpated at intervals during the last months of pregnancy and weekly if the child is not born within one week of the calculated date of delivery, excessive size of the child will rarely escape recognition." Both these writers have advised that the size of the foetus is not necessarily proportionate to the duration of the intra-uterine gestation.

Adair's advice is even more practical. He writes: "In our clinic no definite regime of treatment is followed. Each case is evaluated individually and therapy instituted depending on the conditions found present. Ordinarily it is expectant, the patient being examined each week for excessive size of the fetus and untoward signs. If none be present, she is usually allowed to continue with the pregnancy until natural onset of labour, this being time and again found to be the course least fraught with danger of complications." Note the stress by both the last writers laid on the necessity of the repeated frequent examinations and by the last writer that each case should be judged on its merits. Reynolds sums up these last views with his words: "Is it necessary to have a standard? Is treatment required simply and solely because a pregnancy appears to have continued beyond what we regard as its average duration?"

From what has been quoted it may be fairly stated that little help has been offered to the student or practitioner, at any rate, by British writers. An accurate and more careful assessment of the dates of the last normal menstruation is often advised. The estimation of the height of the fundus will never assist—especially in the last weeks of pregnancy. Girth measurement varies enormously in different women and in any case this measurement does not necessarily increase greatly when the foetus is postmature—this because there is no corresponding increase in the amount of liquor amnii. The engagement or non-engagement of the foetal head at or after term need not help. The foetal head of the truly postmature foetus will stay deeply engaged and low in the pelvic cavity and what is perhaps more misleading, a foetal head that is doubtfully engaged at or about term may easily sink lower as the foetus increases in size to become postmature. The initial hopes that some definite aid might be expected from radiography were soon dashed. Critical observations revealed great variation in the appearance of the various centres of ossification.

The following additional physical signs are put forward to be used in conjunction with pointers that may or may not be present in any of those just mentioned:

(1) When the foetus is truly postmature it is large. Its weight is well above 7 lb. This unusual size can be appreciated on repeated clinical examinations.

(2) Concurrent with the increase in size, is increase in strength. Foetal skeletal muscles develop rapidly in the latter weeks of pregnancy and it is my impression that this development increases even more rapidly in the postmature foetus. Now as these muscles develop, so does the increase in muscle tone become more noticeable. This increase in muscle tone results in the whole foetus becoming more rigid. It is suggested that this rigidity can be recognized on clinical examination. So far, therefore, we have a large foetus and a rigid foetus.

(3) The quantity of liquor amnii in the amniotic sac normally does not appear to increase in the last weeks of pregnancy. One result of this is that as the pregnancy advances it becomes more and more easy to palpate the foetus. In true postmaturity it is often the case that the uterus may be said to be "full of foetus". There is relatively little liquor amnii and everywhere in the uterus there is to be felt some part of the foetus. Thus there may be, and in fact, often there is present a large rigid foetus easily felt in a uterus that contains relatively little liquor, perhaps so little that the uterine wall may be justifiably imagined to outline the foetal position and some of its limbs.

While these signs may be quite obvious, in certain instances, this is not the rule. Their onset and their observation will only be made with reasonable certainty if the

[May 17, 1946]

Full-term Abdominal Pregnancy.—MARY KATHLEEN LAWLOR, F.R.C.S.Ed.

Full-term abdominal pregnancy, occurring in a healthy young primipara, with no history of tubal rupture or vaginal losses during pregnancy, is suggestive of a primary abdominal cyesis.

The mother, aged 26, attended the ante-natal department for the first time in November 1945 at 38 weeks' maturity, with a letter from her doctor stating that the foetus was lying transversely and that he had made two unsuccessful attempts to perform a version. The pregnancy had been complicated by attacks of diarrhoea and vomiting which had always been diagnosed as enteritis.

On examination, it was not difficult to decide that the foetus lying transversely in the upper abdomen was extra-uterine. There was a rounded sub-umbilical swelling which was diagnosed as the placenta and, on vaginal examination, a normal non-pregnant uterus was found lying posteriorly to the placental mass.

Abdominal section confirmed the diagnosis. A perfectly healthy female infant weighing 7 lb. 6 oz. was extracted through a rent in the mesentery. It was lying free in the peritoneal cavity with no liquor amnii. The placenta presented as a highly vascular globular swelling attached to the anterior abdominal wall and the pelvic organs, the view of which it entirely obscured. The umbilical cord was traced to the left-hand corner of the placenta where the foetal membranes were also attached.

Every effort was made to avoid separating the placenta, the vessels of which were of an alarming size, and the abdomen was closed without drainage.

The puerperium was uneventful. The wound healed by first intention. Efforts to establish lactation were unsuccessful and there was no vaginal loss of any kind until the 5th week of the puerperium when an apparently normal period occurred, but was unusual in that it persisted for five weeks. Since then normal monthly periods have taken place, but the 4th and 5th have been a little heavier than usual.

Attacks of diarrhoea and vomiting continued to occur from time to time over 4 months and the patient's general condition was not satisfactory, although the only complaint was tiredness and the only sign the persistent swelling of the placenta left in situ.

This swelling did not show any attempt to decrease in size until the 5th month. There were no signs of calcification or inflammation. The patient began to feel stronger and healthier with the decrease in size of the placenta, which is to-day, May 17, 1946, a tensely, non-tender, cystic swelling about the size of a 14 weeks' cyesis which will presumably disappear by a process of necrosis, liquefaction and absorption.

The baby which is now 6 months old is thriving satisfactorily and is an exceptionally bright and attractive child.

Endometriosis of the Colon.—H. R. ARTHUR, F.R.C.S.Ed.

An unmarried woman, aged 31, complained of pain "all over" the lower abdomen, which she had had with increasing severity for the previous two years. Nothing relevant in her past history. Menstrual history normal, being a 5 day loss in a 28 day cycle, but she stated that she had always had a heavy flow and dysmenorrhoea, and the pain was worse at the time of the menstrual period. The menstrual flow, however, had been no heavier than usual in spite of the extra pain. At the menstrual period, too, her motions were loose and accompanied sometimes by slight bleeding *per rectum*. She had no other symptoms and was able to work as a V.A.D. nurse.

On examination.—Healthy-looking woman with no clinical anaemia; abdomen tender in both lower quadrants, more marked in the left. No mass was palpable. Pelvic examination revealed a normal uterus but with slightly restricted mobility, due to pain. A tender, hard, fixed, irregular mass was palpable in the left side of the pouch of Douglas, apparently adherent to the rectum. The right fornix was clear, the lower genital tract showed no abnormality. All other systems were normal.

Diagnosis.—Pelvic endometriosis with a second differential diagnosis of carcinoma of the ovary.

involve the administration of a stiff dose of castor oil, the induction is accompanied by a variable degree of anxiety which is not alleviated by frequent injections of pitocin and this anxiety is definitely and inevitably increased by each repeated failure to cause the onset of labour. In addition should the induction succeed a considerable proportion of the babies born will be premature although the calculated 40th week was passed. I insist that we should institute a rule in our practice and in our teaching, that if there is a justification for medical induction of labour there is a justification for surgical induction. The full and tedious routine of a medical induction is fully justified when there is a considered necessity for it and should only be embarked upon when the medical attendant has accepted this rule and automatically will perform a surgical induction within a few days of the failure of the medical induction. I have followed this procedure in my own practice, in and out of hospital, for some years and have found no cause to regret doing so.

I instance two very recent cases that illustrate the point I wish to make. The first is that of a primigravida aged 28, who expected her first baby on January 18. From the findings on examinations made during the preceding four to five weeks it became certain that this woman had matured what might be termed "a good strong baby". Therefore on January 18 she was given a routine medical induction. This failed and the membranes were ruptured. Although the foetus appeared large, the foetal head was deeply engaged in the bony pelvis. Labour started and after twenty-four hours she was delivered of a 9 lb. 2 oz. baby by a low forceps operation. The delivery of the shoulders was not easy. This woman might well have not gone into labour if left alone for a fortnight and the delivery then would have been longer and much more difficult. The second case was that of a woman, aged 30, who was expecting her third baby on January 1. At that time and in the preceding weeks the foetus had never appeared large. Her two previous confinements had been normal and the babies had "arrived late" and neither had weighed as much as 7 lb at birth. She was seen each week and labour started naturally on January 24. After four hours' labour she was delivered of a baby weighing 6½ lb. Both these women had been observed regularly from the beginning of pregnancy. In both of them the size of the uterus had been observed in the early months and in both cases this and the date of onset of foetal movements corresponded with the supposed date of onset of the pregnancy.

In conclusion I put the following points forward for consideration. Whereas we shall continue to give to our patients the same estimated date for the confinement, and while we continue as before to take note of the rate of increase in the size of the uterus throughout pregnancy and the time of appreciation of the first foetal movements and any other relevant symptom or sign, we do, from now onwards, cease to teach, that every woman will inevitably mature her baby of 7 lb. weight in the calculated 40 weeks. We should instruct our students that often a normal healthy woman will mature a large, or normal, or small baby in a pregnancy that may last for 40 weeks, or more, or less. Let us abolish any instructions to terminate pregnancy as a routine at the calculated 40th week, 41st week, 42nd week or what you will. Let us teach that by repeated observations at regular intervals during the later weeks of pregnancy there appears a combination of physical signs (which have been described) from which we shall receive guidance to our course of action; and that it may well be as necessary to terminate the pregnancy at the 38th week for a baby that is obviously large, as it might be at the 43rd week, or conversely that in the absence of these definite physical signs let us insist that all interference is bad midwifery. Lastly, let us forbid the administration of a full medical induction unless the indications for induction are such that its failure automatically necessitates a surgical induction.

These tumours were first described in 1927 by Moretti and Arrigoni, and are found most frequently in women past the menopause when they give rise to vaginal bleeding. They have also been recorded in younger women complaining of irregular vaginal bleeding. They are unilateral, solid in consistency and formed of connective tissue cells rich in fat. They secrete oestrogenic hormone.

Schiller believes that these tumours arise from ovarian mesenchyme and regards them as a subgroup of fibromata. Novak, on the other hand, states that they are granulosa-celled tumours which have become luteinized. In support of this latter view, Traut and

Butterworth were able to produce thecomata and granulosa-cell tumours in immature mice by irradiation of the ovaries. This subject has been reviewed by Miss Barnes.

It is a rare tumour with low-grade malignant characteristics, and this case described is of especial interest as it shows the presence of a carcinoma as well, possibly a secondary growth, the primary site of which was in the opposite ovary.

Operation.—At operation several small scattered endometrial nodules were found on the floor of the pouch of Douglas, and the mass was seen to consist of contracted mesocolon, containing endometrial deposits together with a stricture of the bowel at the pelvi-rectal junction. The appearance of the bowel lesion itself suggested a ring carcinoma, but the presence of endometrial deposits in the mesocolon and pelvic peritoneum, together with the complete absence of secondary deposits in the liver or the abdominal cavity, failed to support this diagnosis. The affected area of colon was mobilized and a Paul-Mikulicz resection was carried out in two stages.

Recovery was uneventful; six months later patient was in very good health and back at her job.

Histological examination.—Typical endometrial tissue was found in the muscular wall of the colon.

Comment.—Endometriosis may occur without involvement of the genitalia, so that treatment of this condition may be by the gynaecological surgeon or the general surgeon.

Endometriosis of the colon may be either part of a co-existing pelvic endometriosis or, more rarely, it may be the primary site of the disease. In the first type it is usually a part of the mass of adhesions which is so conspicuous a feature of this lesion, but the wall of the colon may be invaded by ectopic endometrial tissue. The second type of case is less common and the lesion may be a constrictive one, such as the one described, or may be a localized endometrioma, two cases of this latter type being recently described by Mr. Douglas McLeod in his Hunterian Lectures before the Royal College of Surgeons. In either type the important differential diagnosis is from the carcinoma of the bowel, and this may not be made until the abdomen is opened. If a localized tumour is found it may be removed, leaving the bowel lumen intact but if, as was found in this case, a constrictive lesion is present (and the patient is a young woman) resection must be undertaken, with a prognosis, of course, very different from that of a similar case in which the lesion is malignant.

Xanthofibroma Thecocellulare, which became the Site of a Secondary Carcinoma from the Opposite Ovary.—E. W. C. BUCKELL, M.B., B.S., M.R.C.O.G.

Mrs. H., aged 66, para 4. Admitted to University College Hospital 29.12.45. Menopause twenty-four years ago. Complaining of vaginal bleeding for six days, three weeks before admission to hospital.

Examination revealed abdominal ascites and a hard, fixed mass in the pouch of Douglas.

Operation on 1.1.46 revealed bilateral ovarian tumours, measuring about 2 in. diameter with papilliferous growths on their surface. Small papilliferous growths had also invaded pelvic peritoneum. Total hysterectomy and bilateral salpingo-oophorectomy was performed and as much pelvic peritoneum as possible was removed.

Recovery was uneventful. A course of deep X-ray therapy was given about six weeks later.

Follow-up: Last seen on 1.5.46 when the ascites had recurred and in her abdomen a hard mass could be felt rising out of the pelvis.

Specimen consisted of a uterus removed by total hysterectomy together with both appendages. The uterus was of normal size and was lined by a thickened endometrium. A section showed the presence of a number of cystic glands and a dense stroma infiltrated with lymphocytes (metropathia hæmorrhagica) (fig. 1).

The left ovarian tumour measured about 2½ in. by 1½ in. and consisted, for the most part, of two cysts. One cyst measured 1½ in. in diameter and contained blood-stained fluid; there was a fine papilliferous lining. The other cyst was smaller and was not opened. The surface of the tumour was studded with rather larger papilliferous nodules. Section of the growth showed it to be a papilliferous adeno-carcinoma (fig. 2).

The right ovary was replaced by a solid yellowish-white tumour measuring about 2½ in. by 2 in. There was a small cyst at the base of the growth. The surface was also studded with small nodules.

A section showed it to have a stroma analogous to that of a fibroma. It harboured numerous cavities, most of them narrow and elongated and a few short cystic ones. They were lined by a malignant epithelium similar to that seen in the other ovarian tumour (fig. 3). Another section of the growth was stained with Sharlach red. It showed the presence of fat in degenerated cells floating in the lumen of cystic cavities, and also in the stroma cells (fig. 4). The tumour was therefore a xanthofibroma thecocellulare.

These tumours were first described in 1927 by Moretti and Arrigoni, and are found most frequently in women past the menopause when they give rise to vaginal bleeding. They have also been recorded in younger women complaining of irregular vaginal bleeding. They are unilateral, solid in consistency and formed of connective tissue cells rich in fat. They secrete oestrogenic hormone.

Schiller believes that these tumours arise from ovarian mesenchyme and regards them as a subgroup of fibromata. Novak, on the other hand, states that they are granulosa-celled tumours which have become luteinized. In support of this latter view, Traut and

Cervical Missed Abortion.—S. G. CLAYTON, M.S., F.R.C.S.

Patient, aged 30, married for three years. Two years previously she became pregnant, but after three months the uterus ceased to enlarge, and a missed abortion was diagnosed, and evacuated after it had been retained *in utero* for a further four months.

When first seen in January 1944 she stated that her last normal period had been in July 1943. She had slight bleeding in October, and a larger loss with quite severe pain in November. The pain and bleeding ceased, and when seen in January the uterus was of the size of a 14 weeks' pregnancy, and the external os was closed. Missed abortion was diagnosed, but as 600,000 units of œstradiol benzoate were injected without result, the patient was sent home to await spontaneous abortion.

Four months later (in May) nothing more had happened, so the patient was re-admitted. The physical signs were unchanged, and an attempt was made to dilate the cervix with metal dilators. This was astonishingly difficult, and to avoid injudicious violence the cervix was incised before the rounded solid mass of the mole was removed entire, the mass consisting chiefly of foetal bones. On passing a finger into the cavity it was alarming to find a rounded hole in what was thought to be the fundus, but further examination showed that the small body of the uterus was above, and that the mole had been removed from the grossly dilated cervical canal. The cervical incision was stitched and recovery was uneventful.

As judged by a lipiodol hystero-graph the dilated cervix returned to normal in six weeks and no cause for the recurrent abortions was found. A year later the patient became pregnant again and went uneventfully to full term, when she had a normal delivery.

Presumably the gestation was extruded from the uterine cavity at the time that she noticed pain and bleeding, but it is difficult to know why the external os failed to dilate to allow the ovum to pass, as the cervix afterwards appeared perfectly healthy. It is not surprising that œstrogens had no effect if the ovum was in the cervix. It is also curious that the menstrual cycle was not re-established until the mole was evacuated.

Accurate details of her earlier pregnancy could not be obtained, and although it is possible that that also was a cervical abortion there is no proof of that. (Masieri has reported a case in which cervical abortion occurred in two successive pregnancies.)

The condition of cervical missed abortion is clearly described in Taussig's monograph on abortion. It is to be distinguished from rare and genuine cervico-isthmal pregnancy in which the ovum is actually implanted in the isthmus or upper cervix.

Melanoma of the Vulva with Pregnancy.—S. G. CLAYTON, M.S., F.R.C.S.

Patient, aged 27, was eight weeks pregnant in her first pregnancy. She complained of a swelling on the right labium majus, which had been present without alteration for many years. On examination a pedunculated swelling was found, about 4 cm. in diameter, firm in consistency, with somewhat thickened skin over it, but without evident pigmentation. The inguinal glands were not enlarged.

A diagnosis of pedunculated fibroma was made, and in June 1941 the tumour was excised with a fair margin of normal skin. Section unexpectedly showed that the tumour was a melanoma, consisting chiefly of spindle-shaped cells, with very little pigment, and not appearing very active. Further section of the pedicle showed no tumour cells. In view of this fact, and the long history of the tumour, inguinal dissection was not performed, and radiation was not used because of her pregnancy. Her labour was uneventful.

Two years later she was readmitted with an enlarged right inguinal gland. Her general health was good, her liver and spleen were not palpable, and an X-ray of her chest was clear. Bilateral inguinal dissection was performed, and section showed that two glands contained tumour cells similar to those of the primary, except that pigment

was now even less evident. Deep X-ray therapy was directed at the pelvis and inguinal regions. In November 1944 a nodule appeared in the breast, which biopsy proved to be of the same nature, and then further deposits appeared in the liver and bones, and the patient died in January 1945, three and a half years after the original operation.

Comment.—Vulval melanomata are very much rarer than the extensive literature suggests. Up to 1920 Kehrer found 83 case reports, and only 15 later records can be discovered.

The present case is remarkable in two respects: the youth of the patient, and that she was pregnant. In Holland's series (1908) the age was recorded in 33 cases, and 24 of these were over 50 years of age, and no patient was under 30. The average age in Kehrer's series was 54. It is exceptional to encounter a case in the twenties, although Sahler (1927) reported a case aged 28, and Curtis (1933) one aged 29. The latter was practically identical with the present case, and was a primigravida in the last month of her pregnancy, who had a pedunculated mole 1.5 cm. in diameter on one labium majus. This was excised at the time of delivery, and just as in the present case the report that it was a melanoma came as a surprise. Radium was applied to the tumour site and there was no recurrence in five years.

Hirst (1905) described a hyperacute case in a pregnant woman; who died four weeks after the melanoma was first noticed, and Labhardt (1924) and Naviatil (1936) stress the danger of pregnancy in patients with pigmented vulval moles, being of the opinion that pregnancy may stimulate a previously quiescent mole to activity.

In the present case the tumour had been present for some years. Although Holland stated that it is unusual for malignant melanomata to arise from a preceding mole this is certainly not the general opinion, and it would be counter to experience with melanomata arising in other sites; and indeed Gosforth (1926) stresses the danger of minor and incomplete interference with vulval moles.

Although the prognosis with a malignant vulval melanoma is almost hopeless (e.g. Holland reported only one three-year survival among 26 cases) there have been a few reported cures even after repeated partial operations (Meyer, 1907; Fischer, 1881). At Radiumhemmet (Schnagel, 1933) the treatment chosen was diathermy excision combined with X-ray radiation or telerradiation, with one three-year survival out of 4 cases.

It must be admitted that the full menace of this tumour that appeared relatively benign and was of long standing, was not at first realized, and the case strongly emphasizes the danger of all such tumours, particularly in pregnancy.

Ovarian Cyst with Twisted Omental Pedicle.—F. H. FINLAISON, F.R.C.S., M.R.C.O.G.

Mrs. M. W., aged 39, was seen in the autumn of 1945 and complained of intermittent attacks of abdominal pain for the previous ten years. The pains were sharp in character and lasted up to an hour, occurring every two or three weeks. On examination a mobile cystic tumour about 7 in. in diameter was felt in the abdomen. It was slightly tender.

A diagnosis of ovarian tumour with intermittent torsion was made, and laparotomy was performed on October 10, 1945.

Operation: On opening the abdomen the tumour was easily withdrawn, and was found to be attached only to the great omentum, from which it obtained its entire blood supply, and which was twisted through two complete circles. The cyst had come from the right side and the stump of the fallopian tube was still attached to the uterus, but the infundibulo-pelvic ligament had disappeared. The pelvis was quite free from adhesions. The tumour itself was removed by cutting the omentum, and attached to it was the fimbrial end of the fallopian tube with a hydatid of Morgagni. Blood-vessels ran from the omentum to the cyst wall. It appeared to be a dermoid.

Cervical Missed Abortion.—S. G. CLAYTON, M.S., F.R.C.S.

Patient, aged 30, married for three years. Two years previously she became pregnant, but after three months the uterus ceased to enlarge, and a missed abortion was diagnosed, and evacuated after it had been retained *in utero* for a further four months.

When first seen in January 1944 she stated that her last normal period had been in July 1943. She had slight bleeding in October, and a larger loss with quite severe pain in November. The pain and bleeding ceased, and when seen in January the uterus was of the size of a 14 weeks' pregnancy, and the external os was closed. Missed abortion was diagnosed, but as 600,000 units of œstradiol benzoate were injected without result, the patient was sent home to await spontaneous abortion.

Four months later (in May) nothing more had happened, so the patient was re-admitted. The physical signs were unchanged, and an attempt was made to dilate the cervix with metal dilators. This was astonishingly difficult, and to avoid injudicious violence the cervix was incised before the rounded solid mass of the mole was removed entire, the mass consisting chiefly of foetal bones. On passing a finger into the cavity it was alarming to find a rounded hole in what was thought to be the fundus, but further examination showed that the small body of the uterus was above, and that the mole had been removed from the grossly dilated cervical canal. The cervical incision was stitched and recovery was uneventful.

As judged by a lipiodol hystero-graph the dilated cervix returned to normal in six weeks and no cause for the recurrent abortions was found. A year later the patient became pregnant again and went uneventfully to full term, when she had a normal delivery.

Presumably the gestation was extruded from the uterine cavity at the time that she noticed pain and bleeding, but it is difficult to know why the external os failed to dilate to allow the ovum to pass, as the cervix afterwards appeared perfectly healthy. It is not surprising that œstrogens had no effect if the ovum was in the cervix. It is also curious that the menstrual cycle was not re-established until the mole was evacuated.

Accurate details of her earlier pregnancy could not be obtained, and although it is possible that that also was a cervical abortion there is no proof of that. (Masieri has reported a case in which cervical abortion occurred in two successive pregnancies.)

The condition of cervical missed abortion is clearly described in Taussig's monograph on abortion. It is to be distinguished from rare and genuine cervico-isthmial pregnancy in which the ovum is actually implanted in the isthmus or upper cervix.

Melanoma of the Vulva with Pregnancy.—S. G. CLAYTON, M.S., F.R.C.S.

Patient, aged 27, was eight weeks pregnant in her first pregnancy. She complained of a swelling on the right labium majus, which had been present without alteration for many years. On examination a pedunculated swelling was found, about 4 cm. in diameter, firm in consistency, with somewhat thickened skin over it, but without evident pigmentation. The inguinal glands were not enlarged.

A diagnosis of pedunculated fibroma was made, and in June 1941 the tumour was excised with a fair margin of normal skin. Section unexpectedly showed that the tumour was a melanoma, consisting chiefly of spindle-shaped cells, with very little pigment, and not appearing very active. Further section of the pedicle showed no tumour cells. In view of this fact, and the long history of the tumour, inguinal dissection was not performed, and radiation was not used because of her pregnancy. Her labour was uneventful.

Two years later she was readmitted with an enlarged right inguinal gland. Her general health was good, her liver and spleen were not palpable, and an X-ray of her chest was clear. Bilateral inguinal dissection was performed, and section showed that two glands contained tumour cells similar to those of the primary, except that pigment

menopause—are naturally more marked, for at those periods of life there is little or no oestrogenic hormone in the blood.

(2) This case is one of the rare examples of this group of tumours where the malignancy of the tumour is confirmed by clinical findings. It is not possible to diagnose malignancy (in the absence of invasive characteristics) on histological grounds alone. The general impression that granulosa-cell tumours are, in the main, benign, or at most, only locally malignant would appear to be too optimistic. Novak prefers to speak of the tumours not as granulosa-cell tumours but as granulosa-cell carcinomas. He has reviewed a series of 32 cases, and in the follow-up there was a clinical malignancy rate of 28.1%. (Novak & Brauner (1934) *Amer. J. Obstet. Gynec.*, 28, 637).

(3) Some patients do extremely well following upon operation. As it seems likely that there are grades of malignancy in granulosa-cell carcinomas their radical removal should be undertaken even in those cases where the prognosis may seem clinically hopeless.

Myxosarcoma of the Broad Ligament.—E. FRIEDMAN, M.D.

Patient, aged 35, has had one stillborn baby and regular normal periods, except for the last two or three which have been heavier.

Three months ago she noticed enlargement of her abdomen and complained of some frequency and pain in front of the left thigh on lying down. She also had a dry cough. Her general condition, however, was quite good. There was no loss of weight.

On examination a mass arising out of the pelvis was found, irregular, firm, the size of a baby's head and not mobile. The cervix was small and pushed high in the right fornix by a mass in the posterior and left fornix, which appeared to be part of the abdominal tumour. The uterus could not be felt. A provisional diagnosis of intraligamentous fibroids was made.

Operation.—When the abdomen was opened, a mass was found lying in the left broad ligament, immobile and firmly fixed to the bladder, colon and rectum. The uterus, ovaries and both tubes appeared to be normal. Any attempt to remove the tumour would have seriously endangered the patient's life. On section the tumour exuded a glairy mucinous fluid.

Microscopically it was a malignant tumour showing considerable myxomatous degeneration; it was of primitive fibre-forming connective tissue cells.

Comment.—Sarcoma of the broad ligament is rare in the English literature until 1936; the German literature had reported 55 cases up to 1914. Many more have been reported since from the Continent and from the United States.

Although sarcoma can occur in almost any part of the body, those of the broad ligament represent the smallest group. They occur either as a primary tumour, or as a sarcomatous degeneration of a true myoma of the broad ligament. They may also be metastatic. The primary sarcoma, i.e. that which springs from the connective tissue of the broad ligament, is said to be more frequent, more malignant and to give rise to metastasis more rapidly than a secondary sarcomatous growth. It also grows more rapidly.

Histologically it derives from an undifferentiated embryonic tissue which is believed to commence to grow under the stimulus of an impulse such as puberty, trauma or the menopause.

The tumour does not cause typical symptoms so that it can be mistaken for a fibroid, ovarian cyst or a tumour of inflammatory nature. The length of time the tumour has existed before treatment in reported cases varies from one to several years; they are usually found between the ages of 40 and 60.

Treatment.—Deep X-ray therapy might be worth a trial, especially in early cases with no metastases, but the prognosis is bad, even when the tumour has been entirely removed.

Suprarenal Hæmorrhage Complicating the Puerperium.—LOIS E. HURTER, M.B., B.S.

This patient died suddenly of acute bilateral suprarenal hæmorrhage on the 8th day of the puerperium, the cause of the hæmorrhage being obscure.

Case report.—Mrs. W., gravida 2, aged 33, was admitted to hospital on 28.11.45 in the 1st stage of labour. Her previous pregnancy, labour and puerperium had been quite

Recovery was uneventful, and on further questioning the patient recollected that at the beginning of the trouble ten years previously she had been attacked by severe abdominal pain which had persisted for two days.

It would appear that at this time complete torsion of the pedicle had been followed by sloughing of the cyst, but it had acquired a secondary omental attachment and blood supply. The omental pedicle in its turn had undergone intermittent torsion during the ensuing ten years, this accounting for the recurring milder attacks of abdominal pain.

Malignant Granulosa-Cell Tumour.—WILLIAM HAWKSWORTH, F.R.C.S.

Married woman, aged 38, first seen at the Radcliffe Department of Gynæcology, Oxford, on September 11, 1942.

She complained of having a constant desire to open bowels for past six months. Actually passes a motion two to three times a day. No blood or mucus in stools.

Menstrual history.—Menarche, aged 14. Katamenses—3/28; not excessive. Slight hypogastric pain first day of period. L.M.P. 19.8.42.

On examination.—Abdomen: N.A.D. Anal sphincter normal. Vaginal examination: Some laxity of the vaginal walls and introitus, but no cystocele or rectocele. Perineum firm.

Cervix healthy; uterus, anteverted but not enlarged; fornices, clear.

On January 14, 1944 (sixteen months after her first attendance) she reported again with complaint of severe stress incontinence which had been present for three months. Examination now revealed a mass arising out of the pelvis, palpable at the upper border of the symphysis. On bimanual examination this mass was considered to be uterine and probably due to the presence of fibroids. Vaginally there was some vault prolapse associated with cystocele and rectocele.

Operation.—Vaginal hysterectomy revealed a solid ovarian tumour firmly attached to the right lateral wall. The uterus was small and contained one or two seedling fibroids. The vaginal hysterectomy and posterior colpo-perineorrhaphy were completed and then the abdomen was opened. The right ovary was found to be replaced by a fungating mass which had spread laterally to the pelvic wall—this mass was separated with some difficulty from the ureter and iliac vessels and the clearing of the pelvis completed by bilateral salpingo-oophorectomy. Another neoplasm was found involving the terminal ileum about 9 in. from the ileo-caecal valve. The growth in the ileum was resected and an ileo-transverse anastomosis completed the operation. Convalescence was uneventful.

Follow-up: Subsequent examinations, the last being on May 3 of this year, i.e. two years and three months after her operation, have shown this patient to be in excellent health with no evidence of recurrence.

Histology.—The section of the right ovary showed sheets of cells of fairly uniform size with large nuclei. These sheets of cells are arranged more or less into islets, which are separated by small areas of connective tissue. Within the islets themselves there are numerous small spaces in which in some cases can be seen a degenerate nucleus and under a higher power a radial arrangement of cells round these spaces can be identified. These spaces are the typical Call-Exner bodies, and the arrangement of the cells into these islets gives rise to the so-called folliculoid type of this tumour. An identical histological appearance was reproduced in the other ovary and in the deposit in the terminal ileum. In view of these histological features and the way this tumour has spread there can be no doubt that this is a granulosa-cell carcinoma.

Summary.—(1) The characteristic symptomatology of granulosa-cell tumours is well known and although some disturbance of the menstrual rhythm is expected during the reproductive years, this is not always so, as in this case. It has to be remembered that the tumour adds quantitatively to the amount of circulating oestrogenic hormone in the blood, so that during the period of active adult sexual life the hyperoestrinism may be associated with hypermenorrhœa, amenorrhœa, or even with normal menstruation. The changes resulting from the addition of œstrin in the years before puberty or after the

menopause—are naturally more marked, for at those periods of life there is little or no oestrogenic hormone in the blood.

(2) This case is one of the rare examples of this group of tumours where the malignancy of the tumour is confirmed by clinical findings. It is not possible to diagnose malignancy (in the absence of invasive characteristics) on histological grounds alone. The general impression that granulosa-cell tumours are, in the main, benign, or at most, only locally malignant would appear to be too optimistic. Novak prefers to speak of the tumours not as granulosa-cell tumours but as granulosa-cell carcinomas. He has reviewed a series of 32 cases, and in the follow-up there was a clinical malignancy rate of 28.1%. (Novak & Brauner (1934) *Amer. J. Obst. Gynec.*, 28, 637).

(3) Some patients do extremely well following upon operation. As it seems likely that there are grades of malignancy in granulosa-cell carcinomas their radical removal should be undertaken even in those cases where the prognosis may seem clinically hopeless.

Myxosarcoma of the Broad Ligament.—E. FRIEDMAN, M.D.

Patient, aged 35, has had one stillborn baby and regular normal periods, except for the last two or three which have been heavier.

Three months ago she noticed enlargement of her abdomen and complained of some frequency and pain in front of the left thigh on lying down. She also had a dry cough. Her general condition, however, was quite good. There was no loss of weight.

On examination a mass arising out of the pelvis was found, irregular, firm, the size of a baby's head and not mobile. The cervix was small and pushed high in the right fornix by a mass in the posterior and left fornix, which appeared to be part of the abdominal tumour. The uterus could not be felt. A provisional diagnosis of intraligamentous fibroids was made.

Operation.—When the abdomen was opened, a mass was found lying in the left broad ligament, immobile and firmly fixed to the bladder, colon and rectum. The uterus, ovaries and both tubes appeared to be normal. Any attempt to remove the tumour would have seriously endangered the patient's life. On section the tumour exuded a glairy mucinous fluid.

Microscopically it was a malignant tumour showing considerable myxomatous degeneration; it was of primitive fibre-forming connective tissue cells.

Comment.—Sarcoma of the broad ligament is rare in the English literature until 1936; the German literature had reported 55 cases up to 1914. Many more have been reported since from the Continent and from the United States.

Although sarcoma can occur in almost any part of the body, those of the broad ligament represent the smallest group. They occur either as a primary tumour, or as a sarcomatous degeneration of a true myoma of the broad ligament. They may also be metastatic. The primary sarcoma, i.e. that which springs from the connective tissue of the broad ligament, is said to be more frequent, more malignant and to give rise to metastasis more rapidly than a secondary sarcomatous growth. It also grows more rapidly.

Histologically it derives from an undifferentiated embryonic tissue which is believed to commence to grow under the stimulus of an impulse such as puberty, trauma or the menopause.

The tumour does not cause typical symptoms so that it can be mistaken for a fibroid, ovarian cyst or a tumour of inflammatory nature. The length of time the tumour has existed before treatment in reported cases varies from one to several years; they are usually found between the ages of 40 and 60.

Treatment.—Deep X-ray therapy might be worth a trial, especially in early cases with no metastases, but the prognosis is bad, even when the tumour has been entirely removed.

Suprarenal Hæmorrhage Complicating the Puerperium.—LOIS E. HURTER, M.B., B.S.

This patient died suddenly of acute bilateral suprarenal hæmorrhage on the 8th day of the puerperium, the cause of the hæmorrhage being obscure.

Case report.—Mrs. W., gravida 2, aged 33, was admitted to hospital on 28.11.45 in the 1st stage of labour. Her previous pregnancy, labour and puerperium had been quite

Recovery was uneventful, and on further questioning the patient recollected that at the beginning of the trouble ten years previously she had been attacked by severe abdominal pain which had persisted for two days.

It would appear that at this time complete torsion of the pedicle had been followed by sloughing of the cyst, but it had acquired a secondary omental attachment and blood supply. The omental pedicle in its turn had undergone intermittent torsion during the ensuing ten years, this accounting for the recurring milder attacks of abdominal pain.

Malignant Granulosa-Cell Tumour.—WILLIAM HAWKSWORTH, F.R.C.S.

Married woman, aged 38, first seen at the Radcliffe Department of Gynaecology, Oxford, on September 11, 1942.

She complained of having a constant desire to open bowels for past six months. Actually passes a motion two to three times a day. No blood or mucus in stools.

Menstrual history.—Menarche, aged 14. Katamenses—3/28; not excessive. Slight hypogastric pain first day of period. L.M.P. 19.8.42.

On examination.—Abdomen: N.A.D. Anal sphincter normal. Vaginal examination: Some laxity of the vaginal walls and introitus, but no cystocele or rectocele. Perineum firm.

Cervix healthy; uterus, anteverted but not enlarged; fornices, clear.

On January 14, 1944 (sixteen months after her first attendance) she reported again with complaint of severe stress incontinence which had been present for three months. Examination now revealed a mass arising out of the pelvis, palpable at the upper border of the symphysis. On bimanual examination this mass was considered to be uterine and probably due to the presence of fibroids. Vaginally there was some vault prolapse associated with cystocele and rectocele.

Operation.—Vaginal hysterectomy revealed a solid ovarian tumour firmly attached to the right lateral wall. The uterus was small and contained one or two seedling fibroids. The vaginal hysterectomy and posterior colpo-perineorrhaphy were completed and then the abdomen was opened. The right ovary was found to be replaced by a fungating mass which had spread laterally to the pelvic wall—this mass was separated with some difficulty from the ureter and iliac vessels and the clearing of the pelvis completed by bilateral salpingo-oophorectomy. Another neoplasm was found involving the terminal ileum about 9 in. from the ileo-caecal valve. The growth in the ileum was resected and an ileo-transverse anastomosis completed the operation. Convalescence was uneventful.

Follow-up: Subsequent examinations, the last being on May 3 of this year, i.e. two years and three months after her operation, have shown this patient to be in excellent health with no evidence of recurrence.

Histology.—The section of the right ovary showed sheets of cells of fairly uniform size with large nuclei. These sheets of cells are arranged more or less into islets, which are separated by small areas of connective tissue. Within the islets themselves there are numerous small spaces in which in some cases can be seen a degenerate nucleus and under a higher power a radial arrangement of cells round these spaces can be identified. These spaces are the typical Call-Exner bodies, and the arrangement of the cells into these islets gives rise to the so-called folliculoid type of this tumour. Summary.—(1) The characteristic symptomatology of granulosa-cell tumours is well known and although some disturbance of the menstrual rhythm is expected during the reproductive years, this is not always so, as in this case. It has to be remembered that the tumour adds quantitatively to the amount of circulating oestrogenic hormone in the blood, so that during the period of active adult sexual life the hyperoestrinism may be associated with hypermenorrhoea, amenorrhoea, or even with normal menstruation. The changes resulting from the addition of oestrin in the years before puberty or after the

The essential features of the post-mortem report were a yellowish pallor to the skin, but the conjunctivæ were clear. There was a small hæmorrhage beneath lower end of sternum. The upper air passages were congested, there was old tuberculous scarring at the right apex and chronic emphysema of the upper lobes of both lungs. There were patchy areas of hæmorrhage in the right lower lobe. There was no pathological change in the cardiovascular system; in the alimentary system there was an area of hæmorrhage the size of a five-shilling piece into the mucosa of the cardiac end of the stomach and there were small areas of hæmorrhages into the mesenteric attachment of the jejunum. The liver weighed 1,720 grammes. The surface was mottled, there were small hæmorrhages beneath the capsule on the inferior surface. The pattern was coarse and some excess fat was present. The gall-bladder and biliary passages were normal.

The kidneys were pale, the pyramids congested and cortices pale. The pelvis on each side was dilated and congested and there were small hæmorrhages into the pelvis. The right ureter was slightly dilated. The bladder was normal and contained approximately 6 oz. of turbid pale urine. The uterus was well contracted and small subperitoneal fibroids were present. There were small portions of fibrinous clot adherent to lining of uterus. The ovaries were normal with a corpus luteum present in right ovary. The pelvic veins were healthy.

Brain, thyroid gland and pituitary gland appeared normal.

Both suprarenal glands were enlarged, the left weighed 55 grammes and the right weighed 75 grammes (normal weight 5 to 6 grammes). There was hæmorrhage into medullary portions of both glands, the cortices were stretched and thinned.

Histologically the heart muscles showed cloudy swelling, the liver cells were swollen, but there was no evidence of necrosis. The kidneys showed cloudy swelling of the tubule cells.

The suprarenals showed massive hæmorrhage into the medullary portion of the glands extending into and between the cells of the cortex. There was no evidence of thrombosis of the suprarenal vessels.

Comment.—Very few cases of hæmorrhage into the suprarenals in adults have been reported and of these only three have been associated with pregnancy. Hall & Hemkem reported a case in 1936 where there was hæmorrhagic infarction of the suprarenal due to thrombosis of the suprarenal vein in a patient with hyperemesis gravidarum. Keele & Keele in 1942 described a case also due to thrombosis of the suprarenal vein in a patient who had reached the 7th month of pregnancy. The third case, that of massive bilateral suprarenal hæmorrhage associated with necrosis of the liver during the puerperium, was described by Gladys Dodds in 1945.

It appears that the causes of hæmorrhage into the suprarenals are: Acute infective conditions, a general hæmorrhagic state, and in the newborn where there is the possibility of trauma and toxins playing a part.

This case is clinically more like those occurring in acute infections, but there was no evidence of any such infection in life or at the post-mortem examination.

The striking features are the associated small hæmorrhages with a possibility of a general hæmorrhagic state and the presence of shock which has been specifically excluded in other records. A transfusion reaction due to pyrogens has been considered and thought unlikely as no other such reaction occurred although the same citrate solution and same methods of storage had been used for blood given to other patients about the same time.

I should like to thank Miss Gladys Hill for allowing me to report the case.

Pelvic Leiomyosarcoma.—BRAITHWAITE RICKFORD, M.D., F.R.C.S., M.R.C.O.G.

History.—Sister G., unmarried, aged 47, was complaining of an abdominal tumour reaching to the level of the umbilicus. This had been noticed for four months but there were no other symptoms.

On examination.—A smooth firmish doughy tumour was found, reaching to the umbilicus; and on bimanual examination, was thought to be ovarian in origin. A severe uterine hæmorrhage followed admission necessitating a curettage and transfusion. Microscopically the tissue removed was normal post-menstrual endometrium. A month later laparotomy was performed owing to severe abdominal pain. The peritoneal cavity contained a quantity of darkly stained hæmorrhagic fluid and a smooth walled elastic pinkish tumour arising to the level of the umbilicus. In several areas growing

normal and there was no history of any previous illness or operation. Antenatal care had been carried out at the hospital clinic, there had been no oedema, albuminuria or hypertension, the highest recorded blood-pressure being 125/85. Labour progressed normally, a full term, living, male child, weight 8 lb. 6 oz. being delivered spontaneously after twelve and a half hours. During the third stage of labour the patient had a post-partum hæmorrhage of 40 oz. for which no cause was found. The uterus contracted well following the administration of pitocin, 5 units. The general condition was good, the pulse-rate 88 and of good volume. She was given a warm drink and left to rest. Four hours after delivery the patient suddenly became severely shocked, the pulse was rapid and of poor volume, the blood-pressure fell. There was no further bleeding and she did not complain of pain. She responded well to warmth and the administration of two pints of directly compatible group 0 blood, the first pint being run in in one hour and the second pint over a period of three hours. (Group 0 blood was used as Group A was not readily obtainable on that occasion.)

The puerperium was uneventful for seven days apart from mild bronchitis and a moderately severe anæmia; Hb 58%. The uterus involuted well, the patient was apyrexial, the lochia normal and the bowels were open regularly. On the 8th day of the puerperium it was decided to give a further blood transfusion as the anæmia had not responded to iron therapy. A pint of directly compatible macroscopically and microscopically (checked by three observers) group A blood was selected and the transfusion started at 6 p.m. on 5.12.45. At 7.45 p.m. after approximately 5 oz. had run in, the patient complained of acute pain beneath the lower end of the sternum and in both loins; she vomited copiously and was suddenly incontinent of urine and feces. She became cyanosed and collapsed, the pulse was 140 and thready. The blood transfusion was immediately stopped and a sample of the donor's blood saved for repeating compatibility tests.

The diagnosis lay between "incompatible blood transfusion" and "pulmonary embolism".

On examination the patient was restless, cyanosed, breathing was laboured, she lay curled up in bed and resented interference. The chest was clear, the upper abdomen was tender, there was no tenderness in the loins as by this time the loin pain had passed off. Continuous oxygen was given by nasal catheter and finally by a B.L.B. mask. Warmth was applied and an intramuscular injection of 2 c.c. coramine was given. By 9 p.m. the general condition had greatly improved, the colour was good, the pulse below 100 and of better volume, the patient complained of no pain.

As the most likely diagnosis seemed to be incompatibility of the transfused blood, fluids were pressed by mouth and hot packs were applied to the loin, 60 grains of potassium citrate with 30 grains of sodium bicarbonate were given by mouth 2-hourly. By 10 p.m. the pulse had risen again to 130, but as the temperature was 104° this was thought to be reactionary. The patient was restless so morphia grain $\frac{1}{4}$ was given subcutaneously. The patient vomited twice more before midnight, 8 oz. and 6 oz., and one vomit was slightly blood-stained. She had been taking fluids well and appeared thirsty. A Ryle's tube was passed to save the patient the effort of vomiting and was aspirated hourly. An intravenous 5% glucose saline drip was commenced. The colour remained good and apart from restlessness her condition was satisfactory, the pulse remaining about 130. 2 drms. of paraldehyde were given intramuscularly. At 8 a.m. next morning, 6.12.45, the patient suddenly collapsed again and the pulse rose to 160, there was air hunger and she became cyanosed and breathless. By daylight it was possible to see that the skin had a yellowish tinge and the patient appeared dehydrated, though her intake had exceeded her output by 2 pints during the night.

2 c.c. coramine were given, continuous oxygen and 10 minims of 1:1000 adrenalin intravenously. The intravenous drip was changed to 4.285 normal sodium sulphate solution. On examination the patient was profoundly shocked, blood-pressure 40/20, but complaining of no pain. The chest was still clear. A further 2 c.c. of coramine was given intravenously. She rapidly lost consciousness, became comatose and died at 9.45 a.m. 6.12.45 despite all efforts at artificial respiration.

Post-mortem findings.—The compatibility of the donor's cells with the patient's serum and the donor's serum with the patient's cells was repeated and they were found to be directly compatible, macroscopically and microscopically. Death was found to be due to acute adrenal insufficiency caused by acute hæmorrhage into both suprarenals. There was no sign of blood incompatibility or of pulmonary embolism.

Section for the Study of Disease in Children

President—Professor NORMAN B. CAPON, M.D.

[March 22, 1946]

MEETING HELD AT GREAT ORMOND STREET HOSPITAL, LONDON

Hypoproteinaemia.—R. MEYER, M.B., M.R.C.P., for BERNARD SCHLESINGER, M.D., F.R.C.P.

Jean C., aged 3 years. Admitted 14.1.46. *Complaint:* Three weeks swelling of legs and abdomen. Two weeks coryza, loss of appetite, thirst and yellow diarrhoea.

Previous history.—Fit except for pneumonia one year ago and frequent colds.

Diet: Milk one pint daily. Meat once daily. Loves bread, sugar, cereals.

Family history.—Mother, father and 8 siblings alive and well. No complaints.

On examination (14.1.46).—Plump, pink child. Weight 31 lb. Coryza. Large tonsils. Gross oedema of legs, face and trunk. Ascites. Liver—2 fingerbreadths palpable—firm, not tender. No other abnormality including no skin, mucosal, or nerve lesions.

Investigations: Stools yellow and loose. No pathogens. No T.B. Fats: 29.7% dried faeces, 73.8% split. Urine n.a.d. Blood urea 21 mg./100 c.c. Kahn negative.

X-ray: Sinuses clear. Wrists, no abnormality. Chest: heart normal. Small right pleural effusion.

Plasma proteins: 2.55%, alb. 1.82%, glob. 0.73%.

Course: After six days on a light diet without improvement on 20.1.46 she was given thiamine intramuscularly 10 mg. daily for five days and Beminal 1 tab. b.d. by mouth. Oedema lessened the following day and had gone by 22.1.46. Weight dropped 5 lb. in two days and then rose to 27 lb. Liver remained palpable. She was happy and ate well. Discharged 2.2.46 on Beminal 1 tab. t.d.s. and normal diet.

Further investigations.—

	Serum protein	Alb.	Glob.
21.1.46: Takata-ara negative.			
Alk. serum phosph. 6 units.	14.1.46: 2.55%	1.82%	0.73%
24.1.46: Blood urea 23 mg./100 c.c.	21.1.46: 3.96%	—	—
30.1.46: Stool fat 26.3% dried faeces.	24.1.46: 4.54%	3.37%	1.17%
30.1.46: Dextrose tolerance normal.	2.2.46: 4.10%	3.02%	1.08%
30.1.46: Hb. 85% Sahli; W.B.C. 9,800.	22.3.46: 5.94%	3.75%	2.19%

Present weight 28 lb. Liver only just palpable. Symptoms: Coryza still, otherwise well, though restless at night. Impetigo one month ago. Has omitted Beminal tabs. for one month.

Dr. R. Bonham Carter: I would be glad of an explanation of the mechanism by which vitamin-B therapy has relieved the oedema in this case. Hypoproteinaemia, in the absence of renal disease, occurs, so far as I know, only in nutritional disorders in which failure of ingestion or absorption of protein is the cause. In such conditions vitamin-B deficiency might well be associated with hypoproteinaemia but is not necessarily the cause of it.

In about 200 cases of "famine oedema" seen at one P.O.W. camp in Germany no case could be said to have improved by vitamin-B therapy of a massive "blunderbuss" kind. On the other hand mild or early cases improved with rest in bed alone. Most of the prisoners of war had frequency which was directly related to their oedema—that is they were more oedematous when they had less frequency. Nocturnal frequency in these cases could, in part, be controlled by giving an evening meal of relatively high protein

through the tumour wall were thick fleshy exuberances which resembled organized blood clot, being a buffy colour near the tumour and a deep reddish brown at the periphery. The growth was firmly impacted in the pelvis and considered to be malignant. Removal was completed with considerable difficulty and on account of the amount of blood loss pan-hysterectomy was not attempted. The uterus, though adherent to the growth, was not apparently the origin of the tumour. The specimen was largely necrotic in the centre, containing much old blood; in other areas it was pinkish in colour, rather homogeneous in texture and with little if any architecture. A section taken from the most preserved area was reported to be a "fibromyoma with inflammation and necrosis". In view of this radiotherapy was not considered to be indicated.

Five months later a recurrence was present, causing obstruction of the pelvic colon. A colostomy was carried out. A tumour similar to the first was arising from the pelvis and there were large soft pinkish white fleshy secondaries growing over the peritoneum. One of these about $2\frac{1}{2}$ in. high and $\frac{1}{2}$ in. thick was growing at the fundus of the bladder. Its appearance was arresting. The surface of this growth was undergoing rapid fibrillary contractions, corrugating into grooves, resembling the surface of a post-partum uterus, and the whole mass was generally contracting and relaxing like the movements of a jelly-fish, but at a much more rapid rate.

A biopsy was taken from here which was reported to be a "spindle cell sarcoma". The patient died two months later, a post-mortem was performed, and a search was made to elucidate the cause of the twitching of the secondaries. All areas of metastasis were examined microscopically and in a section from a pleural growth unstriated muscle was demonstrated.

The point of interest in this case is the presence of motility in an apparently spindle-celled sarcoma, and the presence of unstriated muscle cells among an area of spindle-celled sarcoma in a distant metastasis, giving strong evidence in support of Handley & Howkins' contention that uterine sarcoma originating in a fibroid always grows from the muscle cells.

REFERENCE

HANDLEY, R. S., and HOWKINS, J. (1937) *Lancet* (ii), 1180, 1246.

Treatment.—She is receiving 15 grains of pancreatin (enteric coated) with each meal. 60 grains a day. Normal diet with no restriction of fat. Vitamin supplements, particularly vitamin-A.

Progress: Her weight gain has been satisfactory since starting pancreatin, she now appears well-nourished though still undersized. However, she is still very susceptible to respiratory infections.

Fibrocystic Disease of the Pancreas.—R. J. PUGH for BERNARD SCHLESINGER, M.D., F.R.C.P.

Female infant, aged 10 months. An only child, born after a normal labour, weighing 7 lb. and completely breast-fed for five months. subsequently partially until weaning was complete at eight months. The patient took her feeds extremely well, never vomited but from birth passed poorly-formed creamy stools, usually twice in the twenty-four hours. These were markedly offensive and exhibited a rancid smell on standing. Since the age of 6 months when the weight reach 14½ lb. there had been no further gain and the stools are said to be "in a yellow oil, passed liquid but solidifying in the pot." For the last three weeks there has been a persistent cough.

Findings: An underweight infant, 14 lb. 5 oz. at 10 months with a good colour, normal contours and no abnormalities to be found on examination.

Stool: Total fat 42.7% of dry weight, 34.4% of which is split. The stool shows excess of undigested and partially digested starch, undigested meat fibres and a slight excess of small fat droplets (Dr. W. W. Payne).

Fat absorption: On a 30 gramme daily dietary, 10.01 grammes fat were lost daily in the stools.

Duodenal enzymes effect no digestion of gelatin up to a 1:3 dilution.

X-ray Chest: Lung fields appear clear.

Treatment.—Mixed dietary to match appetite with pancreatin, grains 60, daily, given in four divided doses a.c. and halibut liver oil mxxv b.d.

Mongol with Abscess in Neck from Tuberculosis of Cervical Spines.—D. ELKIN, M.B., Ch.B., for CHARLES DONALD, O.B.E., F.R.C.S.

M. L., aged 2½ years.

History.—Lump in neck, first noticed by the mother 2½ months ago, steadily increased in size. Child has lost weight over the past six months.

On examination.—Classical mongoloid appearance, bilateral nystagmus. Rounded fluctuant mass in the posterior cervical region, lying under the skin and apparently attached to bone. Full movement in the spine, etc.

Investigations.—Aspirated pus: Thick, creamy, no tubercle bacilli. Mantoux reaction: 1/1,000 positive. X-ray: Pott's disease. Chest normal. C.S.F. normal.

Conclusion: Cervical Pott's disease originating from the spinous processes.

Von Gierke's Disease.—D. ELKIN, M.B., Ch.B., for T. TWISTINGTON HIGGINS, O.B.E., F.R.C.S.

J. B., aged 2 years. Complaint: Swelling of the abdomen, first noticed six months ago, at a time when the child was wasted after pertussis. It increased rapidly at first, but has now seemed stationary for four to six weeks.

On examination.—General condition excellent. Liver grossly enlarged, with a smooth surface, regular outline and firm consistency. Spleen not palpable. Otherwise normal.

Investigations.—Urine and blood normal. Alk. serum phosphatase 14.8 units.

Adrenaline response	Fasting	¼ hr.	½ hr.	¾ hr.	1 hr.
22.2.46: Blood sugar	75	80	106	85	80
22.3.46: " "	59	70	75	78	73

Conclusion: Probably Von Gierke's disease.

After the meeting laparotomy was performed and revealed a smooth pale homogeneous liver. Biopsy confirmed the diagnosis.

Gaucher's Disease.—L. ROWLEY, M.B., for DONALD PATERSON, F.R.C.P.

D. B., male, aged 7½ years, was admitted April 1945. Youngest of a family of four, the other members of which are healthy.

content. This pointed to a direct relationship between protein intake and water balance. Such a relationship has already been described. Lastly, established cases of "famine oedema" require rehabilitation on normal or high protein diet for some weeks before the oedema disappears, and it will reappear, if such men are subsequently subjected to a low protein diet, more quickly in them than in normal subjects upon the same deficient diet.

Rheumatoid Arthritis with Unusual Onset.—B. SCHLESINGER, M.D., F.R.C.P.

A boy aged 4 years was admitted to hospital acutely ill and in some distress. There was a history of a cold with earache three weeks previously, followed by vague joint pains. Acute pericarditis and pleurisy with a small effusion soon developed with high pyrexia. There was no degree of myocarditis other than slight changes in the E.C.G.'s. As his pericarditis subsided, superficial glandular enlargement appeared and typical rheumatoid changes became evident in several joints, particularly the ankles and cervical vertebræ.

Fibrocystic Disease of the Pancreas (Two Cases).—A. D. BARLOW, M.R.C.P., for DONALD PATERSON, F.R.C.P.

(1) Female, born 15.4.45.

History.—Birth-weight 4 lb. 8 oz. Full term. Very slow gain in weight until 6 months old, when she weighed 9 lb. She then developed a cough which persisted for two months increasing in severity till 8 months when she was admitted to Great Ormond Street with bronchopneumonia. Despite an adequate caloric intake she was very undersized. She had taken her feeds well, but her mother had noticed pale undigested stools with a rancid smell since birth.

On admission.—Weight 7 lb. 12 oz. She was cyanosed and dehydrated and grossly emaciated. Moist râles were audible at both bases. Following treatment with penicillin her condition improved and she started to gain weight very slowly. On clinical grounds diagnosis of fibrocystic disease of the pancreas was considered and this was confirmed by the investigations.

Investigations.—Chest X-ray: There is collapse and patchy consolidation in the mid and lower zones of both lungs. Blood-count normal. Stool fats: Total 28.8% of dry faeces. Split fat 19.2%. Duodenal juice: Failure to digest gelatin on two occasions. Serum protein: 5.8 grammes per 100 c.c.

Treatment.—Child was given peptolac (Cow and Gate) with added Savory and Moore's Food. Pancreatin grains 15 was given with each feed.

Apart from a small gain in weight when first admitted her progress has been highly unsatisfactory.

Since the meeting the child has died. Post-mortem confirmed the diagnosis; section of the pancreas showing increased fibrosis and dilatation of the ducts.

(2) G. B., female, born 18.1.40.

History.—Frequent upper respiratory infections since 3 months old. Very poor weight gain. Large abdomen, and large pale offensive motions since 1 year old. Her appetite had always been good.

She is the only child, and there is no relevant family history.

First admitted in June 1942 for intractable rectal prolapse, which was successfully treated by perianal injection of alcohol. At that time she was thought to be a case of coeliac disease. The stool fats were 40.5% (66% split), and contained an excess of undigested meat fibres and starch granules. However, she showed early clubbing, the liver was palpable nearly 1 inch below the costal margin, and an X-ray of her chest showed a mottling at both hila.

She was treated as a case of coeliac disease, but gained little weight.

On 20.5.44 she was readmitted, at 4 years old her weight being 25 lb. Investigations now revealed that she was a case of fibrocystic disease of the pancreas.

Investigations.—Mantoux 1:1,000 neg. Chest X-ray: Rather increased hilar shadows. Blood-sugar tolerance curve (oral): Fasting 84 mg., peak rise 21 mg. Vit. A absorption: Fasting 34 units; after test dose 32 units. Duodenal juice: Gross reduction in trypsin (digestion of gelatin only occurred at 1:6 dilution).

The diagnosis is suggested by the occurrence of persistent chest symptoms in a child showing the clinical picture of coeliac disease, and yet with a good appetite, and is confirmed by the almost complete absence of pancreatic trypsin from the duodenal juice.

Treatment.—She is receiving 15 grains of pancreatin (enteric coated) with each meal. 60 grains a day. Normal diet with no restriction of fat. Vitamin supplements, particularly vitamin-A.

Progress: Her weight gain has been satisfactory since starting pancreatin, she now appears well-nourished though still undersized. However, she is still very susceptible to respiratory infections.

Fibrocystic Disease of the Pancreas.—R. J. PUGH for BERNARD SCHLESINGER, M.D., F.R.C.P.

Female infant, aged 10 months. An only child, born after a normal labour, weighing 7 lb. and completely breast-fed for five months. subsequently partially until weaning was complete at eight months. The patient took her feeds extremely well never vomited but from birth passed poorly-formed creamy stools, usually twice in the twenty-four hours. These were markedly offensive and exhibited a rancid smell on standing. Since the age of 6 months when the weight reach 14½ lb. there had been no further gain and the stools are said to be "in a yellow oil, passed liquid but solidifying in the pot." For the last three weeks there has been a persistent cough.

Findings: An underweight infant, 14 lb. 5 oz. at 10 months with a good colour, normal contours and no abnormalities to be found on examination.

Stool: Total fat 42.7% of dry weight, 34.4% of which is split. The stool shows excess of undigested and partially digested starch, undigested meat fibres and a slight excess of small fat droplets (Dr. W. W. Payne).

Fat absorption: On a 30 gramme daily dietary, 10.01 grammes fat were lost daily in the stools.

Duodenal enzymes effect no digestion of gelatin up to a 1 : 3 dilution.

X-ray Chest: Lung fields appear clear.

Treatment.—Mixed dietary to match appetite with pancreatin, grains 60, daily, given in four divided doses a.c. and halibut liver oil mxv b.d.

Mongol with Abscess in Neck from Tuberculosis of Cervical Spines.—D. ELKIN, M.B., Ch.B., for CHARLES DONALD, O.B.E., F.R.C.S.

M. L., aged 2½ years.

History.—Lump in neck, first noticed by the mother 2½ months ago, steadily increased in size. Child has lost weight over the past six months.

On examination.—Classical mongoloid appearance, bilateral nystagmus. Rounded fluctuant mass in the posterior cervical region, lying under the skin and apparently attached to bone. Full movement in the spine, etc.

Investigations.—Aspirated pus: Thick, creamy, no tubercle bacilli. Mantoux reaction: 1/1,000 positive. X-ray: Pott's disease. Chest normal. C.S.F. normal.

Conclusion: Cervical Pott's disease originating from the spinous processes.

Von Gierke's Disease.—D. ELKIN, M.B., Ch.B., for T. TWISTINGTON HIGGINS, O.B.E., F.R.C.S.

J. B., aged 2 years. Complaint: Swelling of the abdomen, first noticed six months ago, at a time when the child was wasted after pertussis. It increased rapidly at first, but has now seemed stationary for four to six weeks.

On examination.—General condition excellent. Liver grossly enlarged, with a smooth surface, regular outline and firm consistency. Spleen not palpable. Otherwise normal.

Investigations.—Urine and blood normal. Alk. serum phosphatase 14.8 units.

Adrenaline response	Fasting	¼ hr.	½ hr.	¾ hr.	1 hr.
22.2.46: Blood sugar	75	80	106	85	80
22.3.46: " "	59	70	75	78	73

Conclusion: Probably Von Gierke's disease.

After the meeting laparotomy was performed and revealed a smooth pale homogeneous liver. Biopsy confirmed the diagnosis.

Gaucher's Disease.—L. ROWLEY, M.B., for DONALD PATERSON, F.R.C.P.

D. B., male, aged 7½ years, was admitted April 1945. Youngest of a family of four, the other members of which are healthy.

content. This pointed to a direct relationship between protein intake and water balance. Such a relationship has already been described. Lastly, established cases of "famine-œdema" require rehabilitation on normal or high protein diet for some weeks before the œdema disappears, and it will reappear, if such men are subsequently subjected to a low protein diet, more quickly in them than in normal subjects upon the same deficient diet.

Rheumatoid Arthritis with Unusual Onset.—B. SCHLESINGER, M.D., F.R.C.P.

A boy aged 4 years was admitted to hospital acutely ill and in some distress. There was a history of a cold with carache three weeks previously, followed by vague joint pains. Acute pericarditis and pleurisy with a small effusion soon developed with high pyrexia. There was no degree of myocarditis other than slight changes in the E.C.G.'s. As his pericarditis subsided, superficial glandular enlargement appeared and typical rheumatoid changes became evident in several joints, particularly the ankles and cervical vertebrae.

Fibrocystic Disease of the Pancreas (Two Cases).—A. D. BARLOW, M.R.C.P., for DONALD PATERSON, F.R.C.P.

(1) Female, born 15.4.45.

History.—Birth-weight 4 lb. 8 oz. Full term. Very slow gain in weight until 6 months old, when she weighed 9 lb. She then developed a cough which persisted for two months increasing in severity till 8 months when she was admitted to Great Ormond Street with bronchopneumonia. Despite an adequate caloric intake she was very undersized. She had taken her feeds well, but her mother had noticed pale undigested stools with a rancid smell since birth.

On admission.—Weight 7 lb. 12 oz. She was cyanosed and dehydrated and grossly emaciated. Moist râles were audible at both bases. Following treatment with penicillin her condition improved and she started to gain weight very slowly. On clinical grounds diagnosis of fibrocystic disease of the pancreas was considered and this was confirmed by the investigations.

Investigations.—Chest X-ray: There is collapse and patchy consolidation in the mid and lower zones of both lungs. Blood-count normal. Stool fats: Total 28.8% of dry faeces. Split fat 19.2%. Duodenal juice: Failure to digest gelatin on two occasions. Serum protein: 5.8 grammes per 100 c.c.

Treatment.—Child was given peptolac (Cow and Gate) with added Savory and Moore's Food. Pancreatin grains 15 was given with each feed.

Apart from a small gain in weight when first admitted her progress has been highly unsatisfactory.

Since the meeting the child has died. Post-mortem confirmed the diagnosis; section of the pancreas showing increased fibrosis and dilatation of the ducts.

(2) G. B., female, born 18.1.40.

History.—Frequent upper respiratory infections since 3 months old. Very poor weight gain. Large abdomen, and large pale offensive motions since 1 year old. Her appetite had always been good.

She is the only child, and there is no relevant family history.

First admitted in June 1942 for intractable rectal prolapse, which was successfully treated by perianal injection of alcohol. At that time she was thought to be a case of coeliac disease. The stool fats were 40.5% (66% split), and contained an excess of undigested meat fibres and starch granules. However, she showed early clubbing, the liver was palpable nearly 1 inch below the costal margin, and an X-ray of her chest showed a mottling at both hila.

She was treated as a case of coeliac disease, but gained little weight.

On 20.5.44 she was readmitted, at 4 years old her weight being 25 lb. Investigations now revealed that she was a case of fibrocystic disease of the pancreas.

Investigations.—Mantoux 1:1,000 neg. Chest X-ray: Rather increased hilar shadows. Blood-sugar tolerance curve (oral): Fasting 84 mg., peak rise 21 mg. Vit. A absorption: Fasting 34 units; after test dose 32 units. Duodenal juice: Gross reduction in trypsin (digestion of gelatin only occurred at 1:6 dilution).

The diagnosis is suggested by the occurrence of persistent chest symptoms in a child showing the clinical picture of coeliac disease, and yet with a good appetite, and is confirmed by the almost complete absence of pancreatic trypsin from the duodenal juice.

Treatment.—She is receiving 15 grains of pancreatin (enteric coated) with each meal. 60 grains a day. Normal diet with no restriction of fat. Vitamin supplements, particularly vitamin-A.

Progress: Her weight gain has been satisfactory since starting pancreatin, she now appears well-nourished though still undersized. However, she is still very susceptible to respiratory infections.

Fibrocystic Disease of the Pancreas.—R. J. PUGH for BERNARD SCHLESINGER, M.D., F.R.C.P.

Female infant, aged 10 months. An only child, born after a normal labour, weighing 7 lb. and completely breast-fed for five months. subsequently partially until weaning was complete at eight months. The patient took her feeds extremely well never vomited but from birth passed poorly-formed creamy stools, usually twice in the twenty-four hours. These were markedly offensive and exhibited a rancid smell on standing. Since the age of 6 months when the weight reach $14\frac{1}{2}$ lb. there had been no further gain and the stools are said to be "in a yellow oil, passed liquid but solidifying in the pot." For the last three weeks there has been a persistent cough.

Findings: An underweight infant, 14 lb. 5 oz. at 10 months with a good colour, normal contours and no abnormalities to be found on examination.

Stool: Total fat 42.7% of dry weight, 34.4% of which is split. The stool shows excess of undigested and partially digested starch, undigested meat fibres and a slight excess of small fat droplets (Dr. W. W. Payne).

Fat absorption: On a 30 gramme daily dietary, 10.01 grammes fat were lost daily in the stools.

Duodenal enzymes effect no digestion of gelatin up to a 1:3 dilution.

X-ray Chest: Lung fields appear clear.

Treatment.—Mixed dietary to match appetite with pancreatin, grains 60, daily, given in four divided doses a.c. and halibut liver oil mxxv b.d.

Mongol with Abscess in Neck from Tuberculosis of Cervical Spines.—D. ELKIN, M.B., Ch.B., for CHARLES DONALD, O.B.E., F.R.C.S.

M. L., aged $2\frac{1}{2}$ years.

History.—Lump in neck, first noticed by the mother $2\frac{1}{2}$ months ago, steadily increased in size. Child has lost weight over the past six months.

On examination.—Classical mongoloid appearance, bilateral nystagmus. Rounded fluctuant mass in the posterior cervical region, lying under the skin and apparently attached to bone. Full movement in the spine, etc.

Investigations.—Aspirated pus: Thick, creamy, no tubercle bacilli. Mantoux reaction: 1/1,000 positive. X-ray: Pott's disease. Chest normal. C.S.F. normal.

Conclusion: Cervical Pott's disease originating from the spinous processes.

Von Gierke's Disease.—D. ELKIN, M.B., Ch.B., for T. TWISTINGTON HIGGINS, O.B.E., F.R.C.S.

J. B., aged 2 years. Complaint: Swelling of the abdomen, first noticed six months ago, at a time when the child was wasted after pertussis. It increased rapidly at first, but has now seemed stationary for four to six weeks.

On examination.—General condition excellent. Liver grossly enlarged, with a smooth surface, regular outline and firm consistency. Spleen not palpable. Otherwise normal.

Investigations.—Urine and blood normal. Alk. serum phosphatase 14.8 units.

Adrenaline response	Fasting	$\frac{1}{4}$ hr.	$\frac{1}{2}$ hr.	$\frac{3}{4}$ hr.	1 hr.
22.2.46: Blood sugar	75	80	106	85	80
22.3.46: " "	59	70	75	78	73

Conclusion: Probably Von Gierke's disease.

After the meeting laparotomy was performed and revealed a smooth pale homogeneous liver. Biopsy confirmed the diagnosis.

Gaucher's Disease.—L. ROWLEY, M.B., for DONALD PATERSON, F.R.C.P.

D. B., male, aged $7\frac{1}{2}$ years, was admitted April 1945. Youngest of a family of four, the other members of which are healthy.

On examination.—Liver and spleen were found to be enlarged down to the level of his umbilicus, both were firm and hard and the liver surface was irregular. There was no evidence of ascites or portal obstruction and his general condition was good.

Splenectomy and liver biopsy were performed in May 1945. Sections were demonstrated.

	April '45.	Feb. '46.
Serum protein	5.4%	7.3%
Serum cholesterol (normal 100-220) ...	125 mg. %	140 mg. %
Alkaline serum phosphatase (5-15 units)	7.0 units	18.5 units
Prothrombin time (up to 30 secs.) ...	22 secs.	28 secs.
Takata-ara reaction	negative	positive
Blood-count: Red cells 4.9 millions; Hb. 90%; W.B.C. 9,800; polys. 68%; lymphos. 32%.		

He was reinvestigated in February, 1946 as in table above.

Since operation his liver has increased in size and has become more nodular.

Infantilism of Renal Origin.—L. ROWLEY, M.B., for DONALD PATERSON, F.R.C.P.

C. S., male, aged 1 year 7 months. Admitted in January 1946. Vomiting after meals on and off since birth.

He is an only child, born at full term after a normal pregnancy and delivery. His birth-weight was 4 lb. 1 oz. He was bottle fed with frequent changes in brands of dried milks. He was seen to be small for his age but of normal proportions and no abnormal physical signs were elicited.

Height 25 in. (average 30 in), weight 12 lb. (av. 23 lb.), chest 15½ in. (av. 18½ in.), head 17 in. (av. 18½ in.).

He was found to have an insatiable thirst and to be drinking an abnormally large amount of fluid. Routine urine examination showed 85 mg. % albumen.

Blood-count.—R.B.C. 5.3 millions; Hb. 90%; W.B.C. 10,900.

E.S.R. 28 mm. in one hour.

Blood W.R. and Kahn tests negative.

Blood Biochemistry: Serum calcium 9.9 mg. % (9 to 11); inorganic blood phosphorus 5.8 mg. % (4 to 5.5); alkaline plasma phosphatase 2.6 units (10 to 20); plasma proteins 5.31%, normal proportions; plasma bicarbonate 28.2 vols. CO_2 (53 to 77); plasma chlorides 701 mg. % (560 to 630) as NaCl.

Urine: Albumen 85 mg. %. No abnormal deposit.

Blood urea 96 mg. %.

Urea clearance test: (1) 26.1%. (2) 21.6%.

Excretion pyelogram: Dye not concentrated sufficiently to show on X-ray plates.

X-ray: Long bones thin and small, cupping of lower end of ulna; wrists normal ossifications.

Lateral Sinus Thrombosis due to Acute Mastoiditis: Recovery with Penicillin.—H. A. FRASER, for JAMES CROOKS, F.R.C.S.

The patient was a boy aged 7 years who was admitted on 4.3.46 with a history of right earache for one week with purulent otorrhoea for three days following spontaneous perforation of the drum. His mother had noticed a lump in his neck high up on the right side for one day prior to admission. The child had been unwell with lassitude and anorexia for several days but had not had a very high temperature. He had been given inadequate doses of sulphathiazole for four days before admission. There was a past history of recurrent attacks of otitis media since measles at the age of 3 years.

On admission he was an ill, flushed child, T. 103°F., P. 130. Acute right mastoiditis with an abscess about the size of a hen's egg in the neck below the tip of the mastoid process. He was very deaf indeed. Central nervous system normal.

At operation a right cortical mastoidectomy was performed, the lower portion of the lateral sinus being found to be collapsed and thrombosed with a peri-sinus abscess leading to the abscess in the neck. The sinus was not opened, nor ligated, but the wound was packed open with ribbon gauze and a tube inserted for instillation of penicillin, 3,000 units four-hourly. The child was also put on systemic penicillin 10,000 units four-hourly and sulphamezathine in full doses. A total of 161,000 units of penicillin was given locally, and systemic penicillin was continued for a fortnight, total 850,000 units.

The child has made an uninterrupted recovery after running an intermittent pyrexia for two days after the operation, without any sign of rigors or central nervous system involvement.

Influenzal Meningitis.—D. J. CONWAY, M.B., for DONALD PATERSON, F.R.C.P.

M. J., aged 1 year 1 month.

History.—21.2.46: Admitted as an emergency. Collapsed this morning at a Nursery School. Previously quite well. Temp. 100, P. 144. Toxic, slightly cyanosed, neck rigidity and Kernig sign positive. Other systems N.A.D.

C.S.F. turbid and cultured *H. influenza*, type B. Put on sulphadiazine, penicillin intramuscularly and intrathecally also *H. influenza*, type B. antiserum (rabbit) Squibb.

Lumbar puncture C.S.F. percentage	Sulphadiazine	Penicillin intramuscularly	Penicillin intrathecally	<i>H. influenza</i> antiserum
21.2.46: Turbid, protein 320 mg. sugar 52 mg. Chlorides: 680 mg. Cells: 1,283 W.B.C. 307 R.B.C./c.mm. Polys. 99, monos. 1 Culture: <i>H. influenza</i> type B (Pittman)	1 gramme 4-hrly.	8,000 units 4-hrly.	6,000 units

4.3.46: Almost completely well. W.B.C. 6,000. Polys. 34%, lymphos. 62%, monos. 4%.

8.3.46: Discharged home.

Influenzal Meningitis.—D. J. CONWAY, M.B., for BERNARD SCHLESINGER, M.D.

R. H., aged 1 year 5 months.

History.—21.2.46: Taken ill, temperature raised. No physical signs.

1.3.46: Slight injection of right tympanic membrane. Started on a course of sulphamezathine 12½ grammes.

4.3.46: Right paracentesis; a little fluid blood only, temperature 102°-103°. No diarrhoea, vomiting, rashes or pyuria.

15.3.46: Admitted to Great Ormond Street. Pale miserable child. Positive physical signs; small nodular posterior cervical gland, neck rigidity present. Kernig sign negative, fundi normal; knee-jerks rather brisk and plantar responses equivocal.

Lumbar puncture: Turbid C.S.F. No increased pressure. Queckenstedt: no block. Cells 1,000/c.mm. Protein 120 mg.

Culture: *H. influenza* type B (Pittman).

17.3.46: I.V. infusion ½ strength Hartmann's solution with glucose 5% set up.

18.3.46: W.B.C. 27,000. Polys. 81%, lymphos. 19%.

21.3.46: Since admission his general condition has shown very little improvement. Neck rigidity remains. He lies quietly, whimpers when interfered with, eyes usually closed, takes his diet moderately well. Twitched right side of body for ½ minute. Temperature normal today.

- 22.3.46: Twitched right side of body for $\frac{1}{2}$ minute on two occasions. ? Encephalitis.
 23.3.46: Twitched right side of body for $\frac{1}{2}$ minute on six occasions. None after then.
 27.3.46: Sitting up and fairly happy.
 4.4.46: Well, though rather irritable.
 6.4.46: Discharged home.

Comment.—*Haemophilus influenzae* meningitis is an uncommon disease carrying a high mortality rate particularly in those under 5 years of age. *H. influenzae* has been classified by Pittman into six pathogenic types A—F of which type B is most important. It has been shown that this organism has a halo and that in infections a soluble specific polysaccharide can be found in the body fluids and urine much as in pneumococcal infections. The capsular swelling technique forms one of the methods of diagnosis and the reverse method of testing the patients' serum against the organism will show the adequacy of antiserum treatment. The mode of onset of this variety of meningitis may be sudden or a vague illness may only develop meningeal signs after two to three weeks.

The treatment of *H. influenzae* meningitis combines the use of sulphadiazine and antiserum. The use of the two together shows much better results than either singly. Penicillin intramuscularly and intrathecally is now used as well, though the sensitivity of *H. influenzae* to penicillin is not great and very variable. The antiserum is made from rabbits as the molecules are considered to be smaller and thus pass into the C.S.F. more readily. The antiserum has not been used to any great extent in this country, because of shortage of supplies. Certain firms here are commencing its manufacture.

The C.S.F. in *H. influenzae* meningitis is similar to that in pneumococcal or meningococcal meningitis, i.e. turbid C.S.F. of high cell content, mainly polymorphs, decreased sugar and chlorides, and increased protein.

Dr. H. E. Alexander of New York (*Amer. J. Dis. Child.*, 1943, 66, 172), an authority on this type of meningitis, recommends that when all material necessary for determining the causative organism in a purulent meningitis has been obtained, sulphadiazine should be started intravenously.

When *H. influenzae* Type B is isolated an intravenous drip is put up and in the next four hours more sulphadiazine is given and a large quantity of fluid (40 c.c. per kilogram body-weight) in an attempt to speed up urinary excretion of specific soluble substance. During the next two hours the dose of antiserum diluted with Ringer's or physiological saline equivalent to 10 c.c. per kilogram is given by the drip.

The level of C.S.F. sugar before treatment reflects the severity of infection and the dosage of antibody is recommended on the basis: Less than 15 mg. requires 100 mg. of antiserum (estimated as antibody nitrogen), 15 to 25 mg. sugar requires 75 mg., 25 to 40 mg. sugar requires 50 mg. and over 40 mg. sugar/100 c.c. requires 25 mg. of antibody nitrogen.

If after twelve hours the patient's serum does not produce capsular swelling of a suitable suspension of *H. influenzae* in a dilution of 1:10, an extra 25 mg. of antiserum is given and the serum is re-tested a few hours later.

If within twenty-four hours no organisms are seen in the C.S.F., the chlorides and sugar levels have risen, and there is adequate antibody as tested by capsular swelling, no more antibody need be given. If after forty-eight hours satisfactory progress is lacking a dose of antiserum equivalent to 25 mg. of nitrogen is given intrathecally.

The parenteral sulphadiazine in the first twenty-four hours should maintain a blood level of 15 mg. per 100 c.c. Then if the patient appears better 0.1 gramme/kilogram sulphadiazine is administered by mouth up to seven days after the C.S.F. is first shown to be sterile.

Thymoma.—N. F. E. BURROWS, B.M., for W. G. WYLLIE, M.D.

D. L., male, aged 3 months.

A case of a full term, normal labour, breast fed baby. Three weeks ago he started losing weight and vomiting. Stools were constipated, but later became green and slimy. The doctor who was called to see him was unable to palpate the heart apex and found stony dullness over almost the entire anterior chest wall.

He was admitted to Great Ormond Street Hospital on 9.12.44, where these findings were confirmed, and X-ray with barium swallow revealed that the œsophagus was displaced backward by a mass situated anteriorly in the mediastinum, thought to be a tumour of thymic tissue or of nerve tissue origin.

He was given a course of diagnostic X-rays by Dr. Hilton at University College Hospital but this made very little appreciable difference to the size of the tumour. Accordingly, it was considered likely to be of a benign nature, and operation was undertaken by Mr. Denis Browne. A large tumour weighting 350 grammes was removed, which on section proved to be a thymoma.

Convalescence was uneventful, and when last seen (March 1946) he was normal in all respects.

Myasthenia Gravis (Two Cases).—N. F. E. BURROWS, B.M., for W. G. WYLLIE, M.D.

(1) P. N., female, born 9.7.41.

History.—Quite well till October 1944 (aged 3 years) when she developed left ptosis.

Three months later ptosis became bilateral.

Five months after this (June 1945) the left side of her mouth was seen to be drooping, and her face became expressionless. In August 1945 she started tripping easily and fell several times. One day she collapsed and attempted to cough up a lot of phlegm. She became tired very easily, but after an hour's rest symptoms of tiredness and weakness abated somewhat.

Examination and treatment.—She was admitted to Great Ormond Street Hospital on October 17, 1945, as an emergency. She was white, collapsed. Her breathing was almost solely diaphragmatic, and her entire chest was full of moist sounds.

She was given 0.25 mg. prostigmin and 1/150 grain atropine subcutaneously, and in five minutes her breathing deepened, and she made attempts to cough. Ocular movements were restricted to fixed or central vision. She was hardly able to swallow. Pupils large. Reaction to light practically nil (possibly due to atropine). Facial movements weak. Knee-jerks equal and brisk. Arm-jerks brisk, and plantars flexor. Next day she collapsed again in a similar fashion. She became very cyanosed, and after being given 0.5 mg. prostigmin she was put in the Drinker respirator, and tube fed.

- 22.3.46: Twitched right side of body for $\frac{1}{2}$ minute on two occasions. ? Encephalitis.

Comment.—*Haemophilus influenzae* meningitis is an uncommon disease carrying a high mortality rate particularly in those under 5 years of age. *H. influenzae* has been classified by Pittman into six pathogenic types A–F of which type B is most important. It has been shown that this organism has a halo and that in infections a soluble specific polysaccharide can be found in the body fluids and urine much as in pneumococcal infections. The capsular swelling technique forms one of the methods of diagnosis and the reverse method of testing the patients' serum against the organism will show the adequacy of antiserum treatment. The mode of onset of this variety of meningitis may be sudden or a vague illness may only develop meningeal signs after two to three weeks.

The treatment of *H. influenzae* meningitis combines the use of sulphadiazine and antiserum. The use of the two together shows much better results than either singly. Penicillin intramuscularly and intrathecally is now used as well, though the sensitivity of *H. influenzae* to penicillin is not great and very variable. The antiserum is made from rabbits as the molecules are considered to be smaller and thus pass into the C.S.F. more readily. The antiserum has not been used to any great extent in this country, because of shortage of supplies. Certain firms here are commencing its manufacture.

Breathing: Really good clearing cough, which was not possible a few minutes before.

After half an hour she was eating with a spoon a large plate of greens, potatoes and meat, and was able to stand by herself (*see figs.*).

Five hours later the effect of the prostigmin had worn off and she was unable to swallow, had almost complete ophthalmoplegia, and was becoming more expressionless.

A further similar injection was given, and in fifteen minutes she was able to finish her supper without trouble.

FIG. 1.—Before prostigmin.

FIG. 2.—Ten minutes after 0.25 mg. prostigmin.

FIG. 3.—Twenty minutes after 0.25 mg. prostigmin.

A few days later she was given prostigmin orally, 10 mg. four-hourly, later increased to three-hourly, as the effect had waned by the time her next dose was due.

On 5.2.46 Mr. Geoffrey Keynes removed her thymus. Pre-operatively she was given 0.3 mg. prostigmin subcutaneously and post-operatively 0.25 mg.

After a few stormy days post-operatively, she improved, and her dose of prostigmin was reduced from 15 mg. three-hourly to nil. Without any prostigmin she was not so lively and her ptosis was marked, although her general condition was excellent. She was put on a maintenance dose of 5 mg. prostigmin five times a day, and has remained well on this.

The thymus on section was normal, and weighed 5.5 grammes.

Subacute Nephritis.—A. P. NORMAN, M.B., for DONALD PATERSON, F.R.C.P.

C. M., male, aged 5½ years, born 13.11.40.

Previous history and family history not relevant.

} in 24 hours.

B.S.R. 9 mm. in 1 hour.

Urea clearance 100% of normal.

Blood urea 38 mg. %.

Plasma proteins 5.74 grammes %.

Blood-pressure 120/80.

X-ray chest: Heart and lungs normal.

Investigations.—X-ray of thymus showed no evidence of enlargement.

Blood-count: R.B.C. 5,260,000; W.B.C. 26,100.

Progress: Prostigmin dose increased to 0.75 mg. six-hourly and atropine grains 1/150 subcutaneously, without any marked improvement in general condition. Later, one mg. prostigmin four-hourly was given, and her general condition suddenly improved.

On October 21, 1945, she was given 45 mg. prostigmin increased to 60 mg. orally q.d.s. This caused an increase in her chest expansion, but did not affect her ptosis or ocular movements.

She was given rests in the Drinker for a few hours each day until October 28, 1945, when it was discontinued. On October 25 the prostigmin was stopped for thirty hours, and at the end of that time, as her face had become more expressionless, it was restarted at 15 mg. t.d.s.

Prostigmin was stopped for a period of five days in early November, and the child's general condition was still good at the end of this time.

Operation.—On November 13, 1945, her thymus was removed. Prostigmin 1 mg. being given by injection before, and repeated after, operation.

On coming round from the anæsthetic her eyes were wide open and remained thus for four days, although her ocular movements were not full. Her ptosis returned four days later, by which time her dose of prostigmin had been reduced to 15 mg. six-hourly by mouth. A week later her eyes opened better, particularly in the mornings, and a few days after that they were wide open, although ocular movements were poor.

She was discharged from hospital 3.12.45, and has since reported monthly.

Her mother states her eyes are well open, and her ocular movements good in the early morning, but when last seen she had bilateral partial ptosis, and practically no ocular movements. Her general condition was excellent. After her last visit here she was put on prostigmin 5 mg. q.d.s.

The thymus on section was normal, and weighed 17 grammes.

(2) J. B., female, born 14.6.43.

History.—Full-time normal delivery. Birth-weight 7 lb. 15 oz. General condition satisfactory until four weeks before admission when she had drooping of the left lid and left facial weakness. Two weeks later she began to fall to the left when walking, had difficulty in swallowing, and her speech became nasal.

On examination.—Slight ptosis left eyelid and weakness left corner of mouth, with left palatal paralysis.

No wasting or loss of power in the limbs. Fundi normal. Pupils reacted to light and accommodation, but ocular movements restricted. No nystagmus. All reflexes present and normal.

Investigation.—C.S.F.: Clear colourless fluid. Protein: 20 mg.; Sugar: 96 mg.; Chloride: 730 mg.; Culture: Sterile. No cells.

Progress: She was thought to be a case of polyneuritis cranialis, and sent to Great Ormond Street Convalescent Home at Tadworth 22.10.45. Here she gradually improved over a fortnight, but suddenly had an acute central respiratory crisis in which she went black, and had to be given artificial respiration. She improved slightly with tipping, oxygen, strychnine and adrenalin. Her chest was extremely bubbly.

In three days she had got over this attack, but the following day she had another, only less severe.

For four weeks she was moderately well—her facial weakness was improving, she was swallowing more easily—until 28.12.45, when she became cyanosed, and brown fluid poured from her nose and mouth. Breathing became difficult and bubbly. Resuscitation methods tided her over this crisis for forty-eight hours, but her palatal paralysis then became more marked, and she had to be tube fed.

She was readmitted to Great Ormond Street 4.1.46 in poor condition—no intercostal movement, and clear stringy mucoid discharge pouring from her mouth and nose. All reflexes were present but inclined to be sluggish. No papilloedema. Pupils showed sluggish response to light.

Once again she was tipped, given oxygen and atropine. Next day she was improved, but ptosis was marked and her face was completely expressionless. She was able to hold the sides of the cot for a minute or so, and then her arms would flop down on to the bed. Still tube fed.

At this point she was given 0.25 mg. prostigmin and 1/150 grain atropine.

In ten minutes she was more lively, and in twenty minutes her picture was as follows—

Face: Return of expression, smiling with ease.

Eyes: Ptosis improved. Able to raise lids, and eyes able to move.

Deglutition: No signs of milk or saliva as before. Able to swallow.

Breathing: Really good clearing cough, which was not possible a few minutes before.

After half an hour she was eating with a spoon a large plate of greens, potatoes and meat, and was able to stand by herself (*see figs.*).

Five hours later the effect of the prostigmin had worn off and she was unable to swallow, had almost complete ophthalmoplegia, and was becoming more expressionless.

A further similar injection was given, and in fifteen minutes she was able to finish her supper without trouble.

Bronchiectasis Involving all Lobes of Both Lungs Treated by Lobectomy and Multiple Segmental Resections.—Professor R. S. PILCHER, F.R.C.S.

M. O. F., female, born 5.11.32.

History of persistent cough and winter exacerbations since the age of 4 when she had measles and whooping-cough. She had also had a deformity of the front of the chest since this illness. At 10 years of age she was thought to be suffering from bronchiectasis and was admitted for investigation.

Bronchograms showed extensive bronchiectasis affecting on the right side the middle lobe, pectoral segment of the upper and basal segments of the lower, on the left side the lingula and basal segments of the lower lobe. In spite of all lobes being affected there were many segments free of disease and it was decided to attempt radical treatment by multiple segmental resections.

The child was prepared for operation by postural drainage and breathing exercises. She also had her tonsils and adenoids removed and had a bilateral Caldwell-Luc operation. The first operation on the chest was not undertaken until more than a year after diagnosis.

9.11.44: *First operation.*—Right middle lobectomy and resection of the pectoral segment of the upper lobe. It was decided to defer the lower lobe resection. Recovery was straightforward with rapid re-expansion of the residue of the lung.

23.11.44: *Second operation.*—Segmental resection of the right lower lobe with conservation of dorsal segment. There was some delay in re-expansion of the dorsal segment of

the lower lobe but recovery was otherwise straightforward and postoperative bronchogram showed all residual segments re-expanded and no bronchiectasis on the operated side.

The child was allowed to go home for a few months and continued her breathing exercises and postural drainage.

3.1.46: *Third operation*.—Resection of lingula and basal segments of left lower lobe with conservation of dorsal segment. Again there was some delay in re-expansion of the dorsal segment but recovery was otherwise straightforward. Postoperative bronchogram showed residue of both lobes re-expanded and no bronchiectasis.

Vital capacity.—21.10.44: 1,680 c.c. after pre-operative preparation.

25.2.46: 1,220 c.c. after completion of treatment.

Multiple Cysts of the Right Lung and the Right Bronchus.—Professor R. S. PILCHER, F.R.C.S.

R. S., male, born 5.7.39.

In June 1943 he had what was thought to be a right-sided pneumonia and after this had a series of febrile illnesses until January 1945 when he was first seen at Great Ormond Street Hospital. At that time X-ray showed several cysts with fluid levels in the right lung. Since the first illness X-rays had been taken on several occasions and these showed cysts in the right lung varying in size and in their fluid content. The child was kept under observation for several months during which further variations in the X-ray appearances were seen. Bronchograms showed no abnormality except apparent displacement of the bronchi of the right lung by the cysts.

It was thought that there were multiple cysts or a single loculated cyst in the right lung subject to two complications, inflation and infection. As the child had already had several illnesses attributable to these complications it was decided to attempt resection of the diseased part of the lung.

20.9.45: *First operation, resection of cysts*.—Only one large loculated cyst was clearly identified and this was resected with an area of surrounding lung, the main bronchial communication being sutured.

The child made a straightforward recovery but about a month after operation routine X-ray showed what was thought to be a large pneumothorax on the right side, the possibility of a large distended cyst being also considered. There were no symptoms associated with this finding. A large volume of air was aspirated from the right side of the chest and subsequent X-ray showed re-expansion of the lung. Some days later when he was apparently quite well he suddenly cried out and was found very dyspnoeic and fighting to get his breath. Respiration was loud with inspiratory stridor, and cough which had previously been normal was high pitched. There was displacement of the trachea to the left but breath sounds were equal on the two sides and accompanied by loud rhonchi. The dyspnoea subsided spontaneously in a short time but the change in the quality of the cough persisted. It was remarked that the only occasion on which such a cough had been heard before was in a child with compression of the trachea by a bronchial cyst.

In view of these two episodes it seemed probable that there were more cysts in the lung and it was decided to perform a pneumonectomy.

22.11.45: *Second operation, right pneumonectomy*.—One large cyst was seen on the front of the upper lobe. On exposure of the hilum of the lung a tense cyst was found compressing the main bronchus and apparently growing from its wall. It was possible to clear and divide the bronchus above the cyst.

Recovery from operation was straightforward.

Examination of the specimen showed that the cyst was growing from the upper surface of the eparterial bronchus. It is not obvious why the attack of dyspnoea was so sudden. The cyst contained fluid and had not apparently been distended with air.

Vital capacity.—20.7.45: 1,040 c.c. before operation.

11.1.46: 850 c.c. after pneumonectomy.

Calcium Infarction of Renal Tubules in Infancy.—Pathological Specimens shown by REGINALD LIGHTWOOD, M.D.

Clinical history.—V. C., born June 1945, second child of normal parents, was reared on a patent dried-milk food until 6 months old, when gruel and tinned vegetables were given. Shortly afterwards she began to vomit and the mother suspected the vegetables. After a couple of weeks the vomiting diminished without ceasing. At 7 months brought for

President—J. PURDON MARTIN, M.D., F.R.C.P.

[April 4, 1946]

MEETING HELD AT THE NATIONAL HOSPITAL, LONDON

Epileptiform Attacks of Sensations of Taste and Smell: Unilateral Parkinsonian Tremor (Undiagnosed).—G. I. C. INGRAM, M.B., M.R.C.P., for J. PURDON MARTIN, M.D., F.R.C.P.

D. S., aged 30. Four years: attacks of sensation of taste and smell, associated with an alteration of his perception of his environment and with an interference with his train of thought, and with a feeling of fear and with generalized "gooseflesh".

Two years: Parkinsonian type tremor beginning in left arm spreading to left leg three months ago.

Known to have had papillœdema since 1944.

On examination.—Chronic papillœdema, left more marked than right. Left homonymous field defect.

Defective movement of upper and lower left face with set facies. Parkinsonian tremor left arm and leg and set facies.

Investigations.—E.E.G. suggests deep lesion right hemisphere.

Operation by Mr. Harvey Jackson.—Extensive removal of large temporal astrocytoma which extended into the roof of the temporal horn and the floor of the right lateral horn and adjoining structures; subtemporal decompression.

From then on the Parkinsonian tremor in the patient's left arm subsided and the patient improved considerably. Inco-ordination in both left limbs, but there is only slight loss of perception and motor power.

Thoraco-axillary Inlet Syndrome.—G. I. C. INGRAM, M.B., M.R.C.P., for J. PURDON MARTIN, M.D., F.R.C.P.

Mrs. P. R., aged 33. Two and a half and three and a half years ago had her babies: the younger, a boy, was heavy as an infant. She carried them on her left arm.

November 1944 noticed loss of ability to make accurate small movements with the fingers of the left hand.

January 1945 began to notice wasting in the left hand, starting in the thenar eminence and gradually spreading across the palm.

No sensory or trophic symptoms. No pain at all.

Although she has used the other arm for heavy work since the summer, the wasting has progressed in the last six months.

Some attacks of numbness in the right hand at night since January 1946.

On examination.—Severe wasting of T 1 muscles of left hand. No sensory or trophic changes. No changes in the right hand, but easy occlusability of radial pulses on raising either wrist above the shoulder. Left clavicle flatter than the right.

Operation by Mr. Harvey Jackson.—The scalenus anticus fascia was in such a position as to obstruct and press the subclavian artery in an upward direction; and the brachial plexus was compressed between the clavicle and the first rib. The artery was freed by division of the scalenus anticus and the first rib was divided. The patient made an uneventful recovery as far as the operation was concerned but, at the time of discharge,

consultation, because she was losing weight and still liable to vomit, also pale, constipated, and taking feeds very slowly. Vitamins: Given halibut oil, 3 drops a day from 6 weeks old to 5 months old.

18.1.46: *Outpatient*.—Examination: Aged 7 months, weight 14½ lb. General condition poor. Looked ill. Wasted, fretful. Muscles flabby. Divarication of recti. Slight dehydration. No other physical signs. Urine (fresh, non-catheter specimen): Pale yellow: Sp. gr. 1006. Neutral. Trace of albumin. No sugar. Small flocculent deposit, which on microscopical examination showed no casts or red corpuscles, but numerous pus cells and some epithelial cells, a few uric acid crystals, bacilli and cocci. Blood: R.B.C. 4,110,000; Hb. 64%, C.I. 0.79; W.B.C. 9,600; Polys. 36%, basos. 0.5%, lymphos. 56%, large monos. 7.5%.

The infant was admitted to hospital on 1.2.46, aged 7½ months, with a provisional diagnosis of *calcium infarction of renal tubules*: Pale, wasted, lethargic, a weak cry, constipated, slightly inelastic skin. She took her feeds erratically, vomited occasionally and failed to gain. Five days later she developed an infection, the cause of which was not discovered; with sulphamezathine the temperature fell, but still she did not gain.

From 7.2.46 ultraviolet light was given, without benefit. On 13.2.46 the temperature rose again. Sulphamezathine given for four days, and penicillin for eighteen days. She went downhill, and by 16.2.46 looked very ill. The stools became relaxed and soon the constipation had been replaced by diarrhoea. As no source of infection had been discovered, the mastoids were explored under a local anaesthetic, with negative results, on 20.2.46. She died one month after admission in spite of intravenous therapy, blood transfusions, &c.

Pathological findings in hospital.—Urine: 21.1.46. Sp. gr. 1006. Alb. trace; reaction neutral. No casts or R.B.C. Pus cells +++. Epithelial cells +. A few uric acid crystals. *B. coli* and streps.

1.2.46: Neutral. Alb. 10 mg.%. No deposit.

5.2.46: Neutral. Alb. 10 mg.%. W.B.C. 5-10 per high power field. Culture sterile.

12.2.46: Acid. Alb. 10 mg.%. Pus cells 2 per high power field.

5.3.46: Alk. Alb. 200 mg.%. Deposit—NAD. Culture sterile.

Blood urea 4.2.46. 46 mg. per 100 c.c.

Post-nasal swab.—4.2.46: N.A.D. 13.2.46: Pneumococci and *Staph. aureus* coag. pos. 22.2.46: N.A.D.

Rectal swab.—26.2.46: *Ps. pyocyaneus*. Agglutinations. 28.2.46: Neg. to *Salmonella B. typhosus* and *paratyphosus*, *Br. abortus*.

Chest X-ray.—22.2.46: Negative. Mantoux 1/1,000 negative.

In brief, the clinical picture was that of marasmus, with occasional vomiting, constipation, poor appetite, hypotonia, lethargy, and a tendency to dehydration out of proportion to the vomiting. The results of investigation did not seem to account for her condition. The urine was sometimes reported as "normal", and at other times contained traces of albumen, occasional pus cells but no infection; epithelial cells reported in one specimen. The blood urea was somewhat above the upper limit of normality. She died of an intercurrent infection.

Autopsy (Dr. MARTIN BODIAN).—No focus of infection was found. There was oedema of the brain and lungs. The liver showed gross fatty change with faint nutmeg pattern. The kidneys weighed 38 grammes each. Capsules stripped easily. Cortex pale yellow. Pyramids congested. Some degree of foetal lobulation. On cutting into the kidneys there was a gritty feel; the surface of the cross section showed numerous fine greyish-yellow specks in the pyramids especially towards the boundary zone. X-ray of the specimen showed that this material was radio-opaque.

Histology.—Capsule: Normal. Cortex: Many foetal glomeruli. Marked cloudy swelling of convoluted tubules with hyaline casts in many of them. Occasional glomeruli and convoluted tubules showed deposition of calcium sand. *Medulla-pyramids*: Cloudy swelling of collecting tubules with fair number of casts. Also some collecting tubules dilated with desquamation of epithelium and deposition of calcium in lumina. This was the principal distribution of the calcium but some deposits lay outside the tubules. There was no foreign body reaction around these deposits and no evidence of fibrosis. Von Kossa's stain confirmed that the deposits consisted of calcium salts.

Section of Neurology

President—J. PURDON MARTIN, M.D., F.R.C.P.

[April 4, 1946]

MEETING HELD AT THE NATIONAL HOSPITAL, LONDON

Epileptiform Attacks of Sensations of Taste and Smell: Unilateral Parkinsonian Tremor (Undiagnosed).—G. I. C. INGRAM, M.B., M.R.C.P., for J. PURDON MARTIN, M.D., F.R.C.P.

D. S., aged 30. Four years: attacks of sensation of taste and smell, associated with an alteration of his perception of his environment and with an interference with his train of thought, and with a feeling of fear and with generalized "gooseflesh".

Two years: Parkinsonian type tremor beginning in left arm spreading to left leg three months ago.

Known to have had papillœdema since 1944.

On examination.—Chronic papillœdema, left more marked than right. Left homonymous field defect.

Defective movement of upper and lower left face with set facies. Parkinsonian tremor left arm and leg and set facies.

Investigations.—E.E.G. suggests deep lesion right hemisphere.

Operation by Mr. Harvey Jackson.—Extensive removal of large temporal astrocytoma which extended into the roof of the temporal horn and the floor of the right lateral horn and adjoining structures; subtemporal decompression.

From then on the Parkinsonian tremor in the patient's left arm subsided and the patient improved considerably. Inco-ordination in both left limbs, but there is only slight loss of perception and motor power.

Thoraco-axillary Inlet Syndrome.—G. I. C. INGRAM, M.B., M.R.C.P., for J. PURDON MARTIN, M.D., F.R.C.P.

Mrs. P. R., aged 33. Two and a half and three and a half years ago had her babies: the younger, a boy, was heavy as an infant. She carried them on her left arm.

November 1944 noticed loss of ability to make accurate small movements with the fingers of the left hand.

January 1945 began to notice wasting in the left hand, starting in the thenar eminence and gradually spreading across the palm.

No sensory or trophic symptoms. No pain at all.

Although she has used the other arm for heavy work since the summer, the wasting has progressed in the last six months.

Some attacks of numbness in the right hand at night since January 1946.

On examination.—Severe wasting of T 1 muscles of left hand. No sensory or trophic changes. No changes in the right hand, but easy occlusability of radial pulses on raising either wrist above the shoulder. Left clavicle flatter than the right.

Operation by Mr. Harvey Jackson.—The scalenus anticus fascia was in such a position as to obstruct and press the subclavian artery in an upward direction; and the brachial plexus was compressed between the clavicle and the first rib. The artery was freed by division of the scalenus anticus and the first rib was divided. The patient made an uneventful recovery as far as the operation was concerned but, at the time of discharge,

consultation because she was losing weight and still liable to vomit, also pale, constipated, and taking feeds very slowly. Vitamins: Given halibut oil, 3 drops a day from 6 weeks old to 5 months old.

18.1.46: *Outpatient*.—Examination: Aged 7 months, weight 14½ lb. General condition poor. Looked ill. Wasted, fretful. Muscles flabby. Divarication of recti. Slight dehydration. No other physical signs. Urine (fresh, non-catheter specimen): Pale yellow: Sp. gr. 1006. Neutral. Trace of albumin. No sugar. Small flocculent deposit, which on microscopical examination showed no casts or red corpuscles, but numerous pus cells and some epithelial cells, a few uric acid crystals, bacilli and cocci. Blood: R.B.C. 4,110,000; Hb. 64%, C.I. 0.79; W.B.C. 9,600; Polys. 36%, basos. 0.5%, lymphos. 56%, large monos. 7.5%.

The infant was admitted to hospital on 1.2.46, aged 7½ months, with a provisional diagnosis of *calcium infarction of renal tubules*: Pale, wasted, lethargic, a weak cry, constipated, slightly inelastic skin. She took her feeds erratically, vomited occasionally and failed to gain. Five days later she developed an infection, the cause of which was not discovered; with sulphamezathine the temperature fell, but still she did not gain.

From 7.2.46 ultraviolet light was given, without benefit. On 13.2.46 the temperature rose again. Sulphamezathine given for four days, and penicillin for eighteen days. She went downhill, and by 16.2.46 looked very ill. The stools became relaxed and soon the constipation had been replaced by diarrhoea. As no source of infection had been discovered, the mastoids were explored under a local anæsthetic, with negative results, on 20.2.46. She died one month after admission in spite of intravenous therapy, blood transfusions, &c.

Pathological findings in hospital.—Urine: 21.1.46. Sp. gr. 1006. Alb. trace; reaction neutral. No casts or R.B.C. Pus cells ++++. Epithelial cells +. A few uric acid crystals. *B. coli* and streps.

1.2.46: Neutral. Alb. 10 mg.%. No deposit.

5.2.46: Neutral. Alb. 10 mg.%. W.B.C. 5-10 per high power field. Culture sterile.

12.2.46: Acid. Alb. 10 mg.%. Pus cells 2 per high power field.

5.3.46: Alk. Alb. 200 mg.%. Deposit—NAD. Culture sterile.

Blood urea 4.2.46. 46 mg. per 100 c.c.

Post-nasal swab.—4.2.46: N.A.D. 13.2.46: Pneumococci and *Staph. aureus* coag. pos. 22.2.46: N.A.D.

Rectal swab.—26.2.46: *Ps. pyocyaneus*. Agglutinations. 28.2.46: Neg. to *Salmonella*. *B. typhosus* and *paratyphosus*, *Br. abortus*.

Chest X-ray.—22.2.46: Negative. Mantoux 1/1,000 negative.

In brief, the clinical picture was that of marasmus, with occasional vomiting, constipation, poor appetite, hypotonia, lethargy, and a tendency to dehydration out of proportion to the vomiting. The results of investigation did not seem to account for her condition. The urine was sometimes reported as "normal", and at other times contained traces of albumen, occasional pus cells but no infection; epithelial cells reported in one specimen. The blood urea was somewhat above the upper limit of normality. She died of an intercurrent infection.

Autopsy (Dr. MARTIN BODIAN).—No focus of infection was found. There was œdema of the brain and lungs. The liver showed gross fatty change with faint nutmeg pattern. The kidneys weighed 38 grammes each. Capsules stripped easily. Cortex pale yellow. Pyramids congested. Some degree of fetal lobulation. On cutting into the kidneys there was a gritty feel; the surface of the cross section showed numerous fine greyish-yellow specks in the pyramids especially towards the boundary zone. X-ray of the specimen showed that this material was radio-opaque.

Histology.—Capsule: Normal. Cortex: Many fetal glomeruli. Marked cloudy swelling of convoluted tubules with hyaline casts in many of them. Occasional glomeruli and convoluted tubules showed deposition of calcium sand. *Medulla-pyramids*: Cloudy swelling of collecting tubules with fair number of casts. Also some collecting tubules dilated with desquamation of epithelium and deposition of calcium in lumina. This was the principal distribution of the calcium but some deposits lay outside the tubules. There was no foreign body reaction around these deposits and no evidence of fibrosis. Von Kossa's stain confirmed that the deposits consisted of calcium salts.

Tuberculous Spine with Paraplegia.—V. C. SNELL, F.R.C.S.

D. W., female, aged 21, October 1941 complained of aching in back. Treated at Ealing Hospital with infra-red rays and massage.

X-ray (18.2.42) showed partial collapse of D.V.7, which was followed one week later by developing paraplegia. Past history of weakness of left leg. ? Anterior poliomyelitis in early childhood. Patient admitted to St. Vincent's 23.2.42. 27.2.42: Seen by Dr. Purdon Martin. Right plantar reflex extensor. Left not obtainable. Loss of sensation right side D.7 to L.1, left side D.7 to L.4. Postural sense and pyramidal tracts unaffected. 11.3.42: Put on spinal frame. 1.5.42, Dr. Purdon Martin: Sharp sensory level at junction of D.5 and D.6 distribution. Severe loss of sense of position of both feet. Suggest spinal laminectomy to relieve pressure on cord. 23.7.42: Operation by Mr. Snell. D.6 and D.7 drilled to relieve pressure. No pus found.

On 27.7.42 still no improvement in deep reflexes, but some improvement in sensation. 20.11.42, Dr. Purdon Martin: No spinal function. Complete loss of all sensation below level of D.6. Still gross loss of joint sense on either side. Suggest decompression operation.

31.12.42: Operation by Mr. Holmes Sellors. Right costo-transversectomy. Rib was removed from its head from about $\frac{3}{4}$ in. and a large abscess cavity was found underneath. Pleura on the outer side was thickened and in some places calcified and at least a gramme of semicaseous pus was mopped from the wound. The long spinal muscles, which had been retracted inwards, were sutured back and the skin closed.

19.2.43, Dr. Purdon Martin: Still no definite sign of recovery in the cord, but spasms less. 21.5.43, Dr. Purdon Martin: There is some pain sensation, and heat and cold sensation in the right foot. 23.8.43: Report on X-ray. The paravertebral abscess is smaller, there is further kyphos with increased destruction of D.5. 15.11.43, Dr. Purdon Martin: No voluntary movements in lower limbs. Small area of superficial sensation at back of right heel. Legs spastic and all reflexes exaggerated. Some slight sense of position in right lower limb. 3.2.44: Movement returning in both legs, right better than left. 13.3.44: Great improvement in lower limbs. There are now signs of recovered function in all tracts of the spinal cord. Can make good flexion movements with both legs, though there is still a good deal of spasticity in the right, and plantar reflex is still extensor. Pain sensation improved. Position at large joints appreciated, but not toes. To have passive movements to both lower limbs daily in addition to massage. 11.5.44: X-ray shows some consolidation in the spinal lesion. 17.7.44: Improvement continues. Can now recognize position of toes. 20.7.44: To be measured for back support. 11.9.44: Right plantar reflex flexor. No spasticity in either leg. 15.10.44: Commenced walking. 16.3.45: Discharged, wearing double iron and toe-lifting strap on left leg.

Disseminated Sclerosis in one of Uniovular Twins, the other Twin being Similarly Affected.—DENIS WILLIAMS, M.D.

D. C., aged 42, married woman with one healthy child aged 12.

Family history.—Nothing of note except for a similar illness in an identical twin. She has 4 other siblings who are well.

History.—Twelve years ago rapid onset of numbness and loss of sensation in left arm and leg; stiffness of muscles and clumsiness of movement. Partial recovery. Two attacks of double vision, eight and six years ago. Four years ago intermittent pain typical of trigeminal neuralgia; progressive ataxia. Paraplegic symptoms have progressed until the present.

Present condition.—Trigeminal neuralgia in second division on left side (intermittent for the last four months). Clumsiness of left hand and, to a less extent, of right; difficulty in walking and stiffness of legs. Occasional urgency of micturition and constipation.

Past history.—Total hysterectomy three and a half years ago.

On examination.—Cranial nerves and optic discs normal. No nystagmus. Upper limbs—wasting of left arm. Inco-ordination left > right with intention tremor on both sides. Tone increase on left; all tendon-jerks, brisk left > right. Sensation—slight impairment to joint sense, light touch and 2-point discrimination on left. Lower limbs—severe spastic paraplegia; increased jerks, ankle clonus, left > right, and bilateral extensor plantar responses; relative sparing of all forms of sensation. Appreciation of joint sense and light touch slightly impaired in left leg.

W.R. negative. Blood-count normal.

it was too early to see how far her neurological condition had been affected. Power of the intrinsic muscles of the left arm had been very slightly improved.

Lateral Column Degeneration following Nutritional Defects While Prisoners of War in the Far East. Two Cases.—G. I. C. INGRAM, M.B., M.R.C.P., for GEORGE RIDDOCH, M.D., F.R.C.P.

F. A., aged 33; A. W., aged 27. These patients were fed on a diet chiefly of polished rice, and developed symptoms of mental disturbance, visual errors, muscular weakness, bladder incontinence, skin lesions, glossitis and mouth sores, and now show a pure pyramidal lesion affecting the lower legs.

Functional Recovery following Common Peroneal Nerve Suture. Three Cases.—J. E. A. O'CONNELL, F.R.C.S.

(1) H. B., male, aged 49, sustained extensive lacerations of the right calf and popliteal region with an immediate complete lesion of the right common peroneal nerve. At operation (18.5.42) eleven months after injury, a complete lesion with a gap was found and secondary suture performed. Motor recovery commenced four months after operation and progressed satisfactorily.

(2) J. G., male, aged 32, sustained multiple injuries in an air raid, including a laceration in the left popliteal space with an immediate complete lesion of the left common peroneal nerve. At operation (21.3.41) six months after injury, a lesion in continuity with no sparing of fibres was found, excised and secondary suture performed. Motor recovery commenced eleven months after operation and progressed satisfactorily.

(3) G. E., male, aged 32, sustained G.S.W. lateral aspect of right leg with an immediate complete lesion of the right common peroneal nerve. At operation (26.5.45) three and a half months after injury, a lesion in continuity containing several shell fragments was found, excised and secondary suture performed. Motor recovery commenced four months after operation and is progressing.

Comment.—These cases have been shown in order to demonstrate the inaccuracy of the opinion that functional recovery after common peroneal nerve suture is extremely unusual and of poor quality should it occur. They indicate the need for a more rational approach to prognosis as regards motor recovery after peripheral nerve suture. It is not, as might be imagined from what is frequently written on the subject, that some nerves possess an inherent quality which leads to good motor recovery after suture. Rather is it that the extent of motor recovery which follows nerve suture carried out in favourable circumstances is directly proportionate to the size of the muscles which it supplies and the amplitude of the movements which they produce. Thus motor recovery in the muscles of the thigh and upper arm has been excellent after suture of the femoral and musculocutaneous nerves—in one case good function following an inlay cable graft of the latter nerve. In the muscles of the lower leg and forearm useful recovery can be expected. But in the case of the small muscles of the foot and hand the outlook is very different. Recovery of function in the intrinsic muscles of the foot after sciatic nerve suture is probably unknown and, except in lesions of the median and ulnar nerves close to the wrist, useful recovery of function in the small muscles of the hand must be a most unusual occurrence.

Recovery following Suture of Peroneal Nerve.—V. C. SNELL, F.R.C.S.

J. C., female, aged 33. Attended hospital in 1941, with a history of having fallen through a shop window eighteen years previously, sustaining extensive lacerations to the left leg. The foot was fixed in plantar flexion, and the patient complained of aching in the foot and that she caught her foot in carpets, &c.

On 26.2.42 Dr. Purdon Martin recommended exploration of the common peroneal nerve, if the galvanic response was satisfactory. If there was no response, fixation of the foot was planned. There was no response from the tibialis anticus.

25.6.42: *Operation.*—The lower scar was explored. The peroneal nerve was found to be involved in scar tissue and it was divided. Both ends were involved in scar tissue. The ends of the nerve were resected, and the nerve resutured. The knee was plastered at a right angle.

26.8.43: *Operation.*—Right tibialis anticus lengthened by slide operation. Limb plastered.

All muscles are now working. She can walk quite comfortably without any splint or toe-raising spring. She has no pain or aching in the leg.

Tuberculous Spine with Paraplegia.—V. C. SNELL, F.R.C.S.

D. W., female, aged 21, October 1941 complained of aching in back. Treated at Ealing Hospital with infra-red rays and massage.

X-ray (18.2.42) showed partial collapse of D.V.7, which was followed one week later by developing paraplegia. Past history of weakness of left leg, ? Anterior poliomyelitis in early childhood. Patient admitted to St. Vincent's 23.2.42. 27.2.42: Seen by Dr. Purdon Martin. Right plantar reflex extensor. Left not obtainable. Loss of sensation right side D.7 to L.1, left side D.7 to L.4. Postural sense and pyramidal tracts unaffected. 11.3.42: Put on spinal frame. 1.5.42, Dr. Purdon Martin: Sharp sensory level at junction of D.5 and D.6 distribution. Severe loss of sense of position of both feet. Suggest spinal laminectomy to relieve pressure on cord. 23.7.42: Operation by Mr. Snell. D.6 and D.7 drilled to relieve pressure. No pus found.

On 27.7.42 still no improvement in deep reflexes, but some improvement in sensation. 20.11.42, Dr. Purdon Martin: No spinal function. Complete loss of all sensation below level of D.6. Still gross loss of joint sense on either side. Suggest decompression operation.

31.12.42: Operation by Mr. Holmes Sellors. Right costo-transversectomy. Rib was removed from its head from about $\frac{3}{4}$ in. and a large abscess cavity was found underneath. Pleura on the outer side was thickened and in some places calcified and at least a gramme of semicaseous pus was mopped from the wound. The long spinal muscles, which had been retracted inwards, were sutured back and the skin closed.

19.2.43, Dr. Purdon Martin: Still no definite sign of recovery in the cord, but spasms less. 21.5.43, Dr. Purdon Martin: There is some pain sensation, and heat and cold sensation in the right foot. 23.8.43: Report on X-ray. The paravertebral abscess is smaller, there is further kyphos with increased destruction of D.5. 15.11.43, Dr. Purdon Martin: No voluntary movements in lower limbs. Small area of superficial sensation at back of right heel. Legs spastic and all reflexes exaggerated. Some slight sense of position in right lower limb. 3.2.44: Movement returning in both legs, right better than left. 13.3.44: Great improvement in lower limbs. There are now signs of recovered function in all tracts of the spinal cord. Can make good flexion movements with both legs, though there is still a good deal of spasticity in the right, and plantar reflex is still extensor. Pain sensation improved. Position at large joints appreciated, but not toes. To have passive movements to both lower limbs daily in addition to massage. 11.5.44: X-ray shows some consolidation in the spinal lesion. 17.7.44: Improvement continues. Can now recognize position of toes. 20.7.44: To be measured for back support. 11.9.44: Right plantar reflex flexor. No spasticity in either leg. 15.10.44: Commenced walking. 16.3.45: Discharged, wearing double iron and toe-lifting strap on left leg.

Disseminated Sclerosis in one of Uniovular Twins, the other Twin being Similarly Affected.—DENIS WILLIAMS, M.D.

D. C., aged 42, married woman with one healthy child aged 12.

Family history.—Nothing of note except for a similar illness in an identical twin. She has 4 other siblings who are well.

History.—Twelve years ago rapid onset of numbness and loss of sensation in left arm and leg; stiffness of muscles and clumsiness of movement. Partial recovery. Two attacks of double vision, eight and six years ago. Four years ago intermittent pain typical of trigeminal neuralgia; progressive ataxia. Paraplegic symptoms have progressed until the present.

Lower limbs—severe spastic paraplegia; increased jerks, ankle clonus, left > right, and bilateral extensor plantar responses; relative sparing of all forms of sensation. Appreciation of joint sense and light touch slightly impaired in left leg.

W.R. negative. Blood-count normal.

[May 2, 1946]

MEETING HELD AT THE NATIONAL HOSPITAL, QUEEN SQUARE, LONDON
 SYMPOSIUM ON THE SURGICAL TREATMENT OF MYASTHENIA
 GRAVIS

Mr. Geoffrey Keynes said that he believed the main purpose of this meeting was to provide a clinical demonstration of the results of thymectomy for myasthenia gravis, over 30 patients having been assembled for inspection by the members of the Section. He would therefore confine his remarks to an attempt to assess the results and to draw attention to some of the factors which seemed to influence them.

The first question that any physician would naturally ask was what was the mortality of the operation. Mr. Keynes said he had now performed the operation 63 times, but that it was not possible to express the mortality as a percentage of this figure. If the figures were scrutinized chronologically it would be seen that there had been 7 post-operative deaths among the first 21 patients, but only 2 among the next 42. That is to say, it appeared that with increased experience of the operation and post-operative management, the danger had been reduced to a very low figure. This was partly to be attributed to the advice given by Blalock in his original paper to supply the patient after operation with plenty of fluid by means of an intravenous drip. This may have been necessary in the hot climate of Baltimore, but in London it seemed to promote the excessive secretion of mucus to which myasthenic patients were liable, and so to increase the danger to life. This measure had now for some time been omitted.

In addition to the 9 post-operative deaths 4 others had died of the disease, giving a total of 13 patients dead. In 9 others the operation was still too recent for assessment of the result. This left 41 to be assessed. The present figures submitted by Dr. Carson were as follows:

A. Apparently cured, not taking prostigmin	14
B. Very much better, taking small dose of prostigmin	15
C. Slight improvement	3
D. No improvement	9
					<hr/> 41

These results had now been established for periods up to four years, and Mr. Keynes challenged anyone to produce equal results by means of medical treatment or spontaneous remission in any comparable series of patients. All the patients hitherto submitted to operation had been described as severe or very severe examples of the disease. The milder ones had not so far been accepted for surgical treatment.

The results were admittedly erratic, and the reasons for this were still obscure. But scrutiny of the series showed that, on the whole, the best results were obtained in the younger patients with short histories, and the poor results in the older patients with long histories. It was also noticeable that some symptoms, particularly ptosis, tended to remain, even when the patient as a whole had greatly improved.

One factor that plainly influenced the results adversely was the incidence of thymic tumours. There had been 7 of these among the 63 patients, and they inevitably made the operation more difficult and dangerous, owing to their being closely adherent to the pleura and neighbouring structures. Sometimes removal of a thymoma produced great improvement at first, but this might be followed soon by complete relapse and death.

Apart from the presence of a tumour, the size of the gland had no relation to the severity of the disease. The weight varied from 3 to 30 grammes. The histological findings were becoming more definite, and Dr. Collins would describe these.

Mr. Keynes had often been told in past years that myasthenia gravis did not occur in children. Nevertheless the age of his patients had ranged from 56 to 2 years. Recently two patients aged 4 and 2, had been operated on at Great Ormond Street Hospital, under the care of Dr. Wyllie. Both children were moribund when admitted, but had responded to prostigmin, and since operation had recovered completely except for persistent ptosis in one of them. The child of 4 was now described by her father as "tireless".

As a pendant to his remarks Mr. Keynes referred to a communication he had received from Dr. Viets, of the Massachusetts General Hospital, Boston. Dr. Viets had submitted 16 patients to operation but for the time being had abandoned this form of treatment. Mr. Keynes suggested that this was probably due to two factors: (1) the operative mortality of 5 in 16, the same rate as in the first 21 of Mr. Keynes' patients, (2) the high incidence of tumours, also 5 in 16, a factor which Mr. Keynes had already shown to influence results adversely.

The taking of prostigmin after operation was influenced to some extent by the psychology of the patients. On the one hand there were some who were so determined to register improvement that they tended to reject prostigmin even when they really needed it. On the other hand there were those who had become so habituated to the drug that they had a feeling of insecurity without it, even when it was not necessary. The second category was illustrated by one of the patients present at the demonstration, who was taking "one tablet a week", this being on Saturday afternoons with a view to a dance in the evening.

Mr. Keynes concluded that the results he had obtained on the whole justified the further performance of thymectomy. There was also evidence in favour of operating early, now that the operation had become almost safe, before the disease had become chronic. Early operation might also forestall the formation of thymomas, the high incidence of which was a serious factor influencing results.

Dr. Douglas H. Collins: *Notes on the pathology of the thymus glands removed in the surgical treatment of myasthenia gravis.*—Perhaps the scarcity of morbid appearances is the most astonishing feature in the pathological anatomy of the thymus glands removed from patients with myasthenia gravis. Gross structural abnormalities of the gland are the exception rather than the rule. Tumours of the gland, as will be shown, occur only in a proportion of 1 in 7 of the cases. The remaining glands differ hardly at all from the normal in their appearance to the naked eye, though there are some qualitative differences in their histology.

Dr. A. B. Bratton and I are examining these glands together. Our series and its statistical analysis are not yet complete; a more detailed paper will be published elsewhere. There are certain features of the glands constant enough to enable us to state with some confidence whether or not a gland comes from a case of myasthenia gravis when examining unlabelled sections under the microscope. It may be of value at this stage to describe in broad terms some of the pathological characteristics of the thymus in myasthenia gravis, so that they may be here recorded.

There are three main headings: (1) The normal thymus; (2) thymic tumours in myasthenia gravis; (3) non-tumour glands from myasthenic cases. In all we have so far examined 56 glands from patients with myasthenia, two of which came to post-mortem before operation, and a number of normal glands as control material.

The normal thymus.—Normal thymus glands for control purposes have been sought amongst Dr. Bratton's large material and also in my own small series of 10 healthy persons who died sudden, accidental deaths. Ordinary hospital post-mortem material does not provide satisfactory controls as atrophy of the thymus occurs very rapidly in malnutrition, infective, or cachectic diseases. Amongst normals the weight of the individual thymus is extremely variable. The shape is somewhat more constant according to age-group, varying from a solid conoid or cordate gland in infancy to the elongated bilobed gland of the adult. Qualitative changes, best seen under the microscope, also tend to be constant in the different age-groups. At adolescence fat replacement along the lines of the fibrous intersections of the gland commences and advances into the typical adult type in which only islets of thymic tissue are found floating in fat. These islets in the normal person are mainly of medullary tissue. Hassall bodies persist and probably continue to be formed throughout adult life, though cornification and calcification of these may be seen at any age. The large lymphoid cortical foci seen in the childhood gland are reduced in adult life to only a thin rim of lymphocytes or an occasional small rounded follicle. The small lymphocytes, or thymocytes, become less closely packed in the adult medullary tissue. It is particularly noteworthy that the amount of parenchymatous tissue in a gland cannot be assessed without microscopic section, and that a gland which to the naked eye looks solid and fleshy may, on section, be found to have only some 20 to 40% of glandular tissue. Bratton has used a method of floating a gland in water as a rough assessment of this, the infiltrated fat lending buoyancy to the organ.

[May 2, 1946]

MEETING HELD AT THE NATIONAL HOSPITAL, QUEEN SQUARE, LONDON
 SYMPOSIUM ON THE SURGICAL TREATMENT OF MYASTHENIA
 GRAVIS

Mr. Geoffrey Keynes said that he believed the main purpose of this meeting was to provide a clinical demonstration of the results of thymectomy for myasthenia gravis, over 30 patients having been assembled for inspection by the members of the Section. He would therefore confine his remarks to an attempt to assess the results and to draw attention to some of the factors which seemed to influence them.

The first question that any physician would naturally ask was what was the mortality of the operation. Mr. Keynes said he had now performed the operation 63 times, but that it was not possible to express the mortality as a percentage of this figure. If the figures were scrutinized chronologically it would be seen that there had been 7 post-operative deaths among the first 21 patients, but only 2 among the next 42. That is to say, it appeared that with increased experience of the operation and post-operative management, the danger had been reduced to a very low figure. This was partly to be attributed to the advice given by Blalock in his original paper to supply the patient after operation with plenty of fluid by means of an intravenous drip. This may have been necessary in the hot climate of Baltimore, but in London it seemed to promote the excessive secretion of mucus to which myasthenic patients were liable, and so to increase the danger to life. This measure had now for some time been omitted.

In addition to the 9 post-operative deaths 4 others had died of the disease, giving a total of 13 patients dead. In 9 others the operation was still too recent for assessment of the result. This left 41 to be assessed. The present figures submitted by Dr. Carson were as follows:

A. Apparently cured, not taking prostigmin	14
B. Very much better, taking small dose of prostigmin	15
C. Slight improvement	3
D. No improvement	9
					<hr/> 41

These results had now been established for periods up to four years, and Mr. Keynes challenged anyone to produce equal results by means of medical treatment or spontaneous remission in any comparable series of patients. All the patients hitherto submitted to operation had been described as severe or very severe examples of the disease. The milder ones had not so far been accepted for surgical treatment.

The results were admittedly erratic, and the reasons for this were still obscure. But scrutiny of the series showed that, on the whole, the best results were obtained in the younger patients with short histories, and the poor results in the older patients with long histories. It was also noticeable that some symptoms, particularly ptosis, tended to remain, even when the patient as a whole had greatly improved.

One factor that plainly influenced the results adversely was the incidence of thymic tumours. There had been 7 of these among the 63 patients, and they inevitably made the operation more difficult and dangerous, owing to their being closely adherent to the pleura and neighbouring structures. Sometimes removal of a thymoma produced great improvement at first, but this might be followed soon by complete relapse and death.

Apart from the presence of a tumour, the size of the gland had no relation to the severity of the disease. The weight varied from 3 to 30 grammes. The histological findings were becoming more definite, and Dr. Collins would describe these.

Mr. Keynes had often been told in past years that myasthenia gravis did not occur in children. Nevertheless the age of his patients had ranged from 56 to 2 years. Recently two patients aged 4 and 2, had been operated on at Great Ormond Street Hospital, under the care of Dr. Wyllie. Both children were moribund when admitted, but had responded to prostigmin, and since operation had recovered completely except for persistent ptosis in one of them. The child of 4 was now described by her father as "tireless".

As a pendant to his remarks Mr. Keynes referred to a communication he had received from Dr. Viets, of the Massachusetts General Hospital, Boston. Dr. Viets had submitted 16 patients to operation but for the time being had abandoned this form of treatment. Mr. Keynes suggested that this was probably due to two factors: (1) the operative mortality of 5 in 16, the same rate as in the first 21 of Mr. Keynes' patients, (2) the high incidence of tumours, also 5 in 16, a factor which Mr. Keynes had already shown to influence results adversely.

The taking of prostigmin after operation was influenced to some extent by the psychology of the patients. On the one hand there were some who were so determined to register improvement that they tended to reject prostigmin even when they really needed it. On the other hand there were those who had become so habituated to the drug that they had a feeling of insecurity without it, even when it was not necessary. The second category was illustrated by one of the patients present at the demonstration, who was taking "one tablet a week", this being on Saturday afternoons with a view to a dance in the evening.

Mr. Keynes concluded that the results he had obtained on the whole justified the further performance of thymectomy. There was also evidence in favour of operating early, now that the operation had become almost safe, before the disease had become chronic. Early operation might also forestall the formation of thymomas, the high incidence of which was a serious factor influencing results.

Dr. Douglas H. Collins: *Notes on the pathology of the thymus glands removed in the surgical treatment of myasthenia gravis.*—Perhaps the scarcity of morbid appearances is the most astonishing feature in the pathological anatomy of the thymus glands removed from patients with myasthenia gravis. Gross structural abnormalities of the gland are the exception rather than the rule. Tumours of the gland, as will be shown, occur only in a proportion of 1 in 7 of the cases. The remaining glands differ hardly at all from the normal in their appearance to the naked eye, though there are some qualitative differences in their histology.

Dr. A. B. Bratton and I are examining these glands together. Our series and its statistical analysis are not yet complete; a more detailed paper will be published elsewhere. There are certain features of the glands constant enough to enable us to state with some confidence whether or not a gland comes from a case of myasthenia gravis when examining unlabelled sections under the microscope. It may be of value at this stage to describe in broad terms some of the pathological characteristics of the thymus in myasthenia gravis, so that they may be here recorded.

There are three main headings: (1) The normal thymus; (2) thymic tumours in myasthenia gravis; (3) non-tumour glands from myasthenic cases. In all we have so far examined 56 glands from patients with myasthenia, two of which came to post-mortem before operation, and a number of normal glands as control material.

The normal thymus.—Normal thymus glands for control purposes have been sought amongst Dr. Bratton's large material and also in my own small series of 10 healthy persons who died sudden, accidental deaths. Ordinary hospital post-mortem material does not provide satisfactory controls as atrophy of the thymus occurs very rapidly in malnutrition, infective, or cachectic diseases. Amongst normals the weight of the individual thymus is extremely variable. The shape is somewhat more constant according to age-group, varying from a solid conoid or cordate gland in infancy to the elongated bilobed gland of the adult. Qualitative changes, best seen under the microscope, also tend to be constant in the different age-groups. At adolescence fat replacement along the lines of the fibrous intersections of the gland commences and advances into the typical adult type in which only islets of thymic tissue are found floating in fat. These islets in the normal person are mainly of medullary tissue. Hassall bodies persist and probably continue to be formed throughout adult life, though cornification and calcification of these may be seen at any age. The large lymphoid cortical foci seen in the childhood gland are reduced in adult life to only a thin rim of lymphocytes or an occasional small rounded follicle. The small lymphocytes, or thymocytes, become less closely packed in the adult medullary tissue. It is particularly noteworthy that the amount of parenchymatous tissue in a gland cannot be assessed without microscopic section, and that a gland which to the naked eye looks solid and fleshy may, on section, be found to have only some 20 to 40% of glandular tissue. Bratton has used a method of floating a gland in water as a rough assessment of this, the infiltrated fat lending buoyancy to the organ.

Thymic tumours in myasthenia gravis.—Tumours of the gland recognizable either by the naked eye or by the microscope have been found in only eight cases (14.3%). They have been found more commonly in the severer forms of the disease. These tumours have not been uniform in type. They are sometimes localized in one part of the organ or diffused through the whole. Their histology varies within the range of cell types described as lympho-epithelioma or thymoma.

From a survey of the literature it would appear that the incidence of myasthenia gravis in cases of thymic tumour is much greater than the incidence of thymic tumours in cases of myasthenia.

Non-tumour, thymus glands in myasthenia gravis.—In myasthenia gravis, apart from glands containing tumour, the thymus does not differ in size or in gross appearance from the normal adult type and it does not markedly differ in the percentage of parenchymatous tissue in relation to fat and stroma substance. The conception of persistent thymus should, therefore, I think, be abandoned, but microscopically there are two characteristics which differentiate the myasthenic gland from the normal. The first is a qualitative difference in the surviving islets of parenchyma. Most myasthenic glands show a denser concentration of lymphocytes in the cortex, in other words, cortical atrophy is less marked than in the normal. Many islets show well-rounded lymphoid cortical foci and lymphocytes—or as some would prefer to call them, small thymocytes—are more thickly scattered about the medulla. The second characteristic is more peculiar. This is the formation within the medulla of structures apparently identical with the germ centres or secondary nodules of Flemming commonly seen in lymph glands. These are regularly rounded or slightly oval areas of clearer tissue circumscribed by concentric rings of small darkly-staining cells of lymphoid type. In the clear centre there are oval, vesicular, pale, nuclei fairly evenly distributed and lying within large cells whose cell walls and divisions are difficult to demonstrate. The uniformity of this cell mass is interrupted by spaces which may possibly be rudimentary lymphatic channels, but are more likely to be vacuolated degenerating cells containing nuclear fragments. Nuclear mitoses are also often seen in these germ centres, which have been found in two-thirds of myasthenic thymuses (28 out of 42 non-tumour glands) and have been found once in the surviving tissue around a tumour. In silver-stained preparations, these germ centres are not penetrated by the argentophil fibrils which are interlaced among the epithelial tissue of the thymic medulla. Their relation with lymphoid tissue is supported by this fact and by their corona of lymphocytes which are not otherwise so arranged in the medulla. In my opinion the presence of these structures in so many myasthenic glands is statistically significant. They were first described only in 1924 by Jolly and de Tannenberg in the thymus of a normal cat as something quite exceptional. Bratton has seen them in only three instances among a large number of non-myasthenic glands and I have not encountered them among my own normal material.

Hassall bodies do not appear to vary between normal and myasthenic glands. In a few cases of myasthenia gravis one finds also a packed syncytial concentration of clear cells of the medulla which might be regarded either as medullary hyperplasia or as the early formation of germ centres before they collect their lymphocytes.

Interpretation of these findings is impossible at present, but it would seem that the thymus in myasthenia reacts in a manner more characteristic of lymphoid tissue than of an epithelial organ. One cannot postulate a specific function for these germ centres, as we do not know their function in lymph nodes, and in the thymus these structures do not appear different from the secondary nodules or germ centres which appear in many other organs as well as lymph glands; for example, the toxic thyroid, where there is an associated lymphoid infiltration.

SUMMARY

(1) Only a proportion of about 1 in 7 thymus glands bear recognized tumours in a series of cases of myasthenia gravis.

(2) Persistence of the thymus beyond the age of expected involution is a hazy conception and is not one on which the relation between the gland and myasthenia gravis can be explained.

(3) The majority of the glands in myasthenia gravis do not show any gross anatomical abnormality.

(4) Qualitative changes in the histology of non-tumour glands in myasthenia gravis are significantly common. They are such as to indicate a reaction of the pattern charac-

teristic of a lymphoid tissue, but whether these are related to the cause or to the effects of myasthenia gravis cannot be judged.

(5) The tissue elements more specific to the thymus, i.e. reticulated medullary epithelium and the Hassall bodies, have not so far been shown to undergo any constant or significant change in myasthenia gravis except in the case of tumours where both lymphoid and epithelial elements are concerned in the new growth.

Dr. Purdon Martin (Chairman): My first impression was one of disappointment that so many patients were still taking prostigmin. Moreover, we are told that 9 patients who were operated on have not improved, and 3 others only slightly, while 5 died in addition to those who had tumours. From these results it is evident that thymectomy is not the whole answer to myasthenia.

On the other hand, 14 patients are able to do without prostigmin, and lead normal lives, and the results are best in the young people.

We must ask ourselves in the first place what would have been the mortality in these cases if no operations had been performed. The disease is one with which we were quite familiar before the operation was introduced and we can recall what the results were. It was always a more severe disease in the young people. Over a considerable number of years before the introduction of prostigmin I never saw a patient under the age of 25 survive for more than twelve months, and it was rare for them to do anything other than go steadily downhill. It is precisely with these young patients that Mr. Keynes reports his best results. Whether the thymus has anything directly to do with myasthenia or not, for these patients the operation does something which is dramatic and life-saving.

The two children who have been shown are extreme examples of this. It happened that by the kindness of Dr. Wyllie I saw both of them before they were operated on—one of them was just surviving in a Drinker respirator—and making such allowances as my experience permits me to make for the possibility of remission on the point of death, I cannot believe that they would both be as they are this evening, or be here at all, if they had not had the operation. That then is my conclusion as regards the young people.

Of the older patients many, especially since the arrival of prostigmin, passed into a chronic state—sometimes a little better, sometimes a little worse. In many cases only the ocular muscles and face were affected, and in others the muscles of the jaw and throat as well. In such cases the effects of the operation are less definite. We are told that 15 patients improved greatly and 3 others moderately.

A point which should be considered is, when the improvement took place in relation to the operation. If improvement occurred at once, then we should attribute it to the operation, but if it did not occur till some months afterwards, it would be safer in assessing the results to attribute it to the effects of a remission. I feel that Mr. Keynes and Dr. Carson can afford to make that concession to the critics, because recalling my experience of this disease in the past, I can only conclude that on whatever it is based, the operation represents a great advance in the treatment of a disease which had a very high mortality.

Sir Charles Symonds said that, having examined the cases and heard Mr. Geoffrey Keynes's report, he had no doubt that thymectomy represented a very great advance in the treatment of myasthenia gravis. Spontaneous remissions were well known, and he had personal experience of several striking examples, but he was sure that the average expectation of health and life in this disease had been much less than that now offered by surgery. It would, however, be valuable to compare with Mr. Keynes' series, a series of control cases followed over a number of years in the pre-prostigmin days and in the prostigmin period, without operation. Myasthenia gravis was a rare disease, and it would be necessary in any investigation of this sort to pool the experience of neurologists.

Dr. L. P. E. Laurent: Mr. Keynes' patients certainly show some very remarkable examples of complete remission of symptoms, but my experience of myasthenia gravis in the past eighteen years, extending to some 65 cases, has led me to believe that the

Thymic tumours in myasthenia gravis.—Tumours of the gland recognizable either by the naked eye or by the microscope have been found in only eight cases (14.3%). They have been found more commonly in the severer forms of the disease. These tumours have not been uniform in type. Dr. Purdon Martin (Chairman): My first impression was one of disappointment that so many patients were still taking prostigmin. Moreover, we are told that 9 patients who were operated on have not improved, and 3 others only slightly, while 5 died in addition to those who had tumours. From these results it is evident that thymectomy is not the whole answer to myasthenia.

On the other hand, 14 patients are able to do without prostigmin, and lead normal lives, and the results are best in the young people.

We must ask ourselves in the first place what would have been the mortality in these cases if no operations had been performed. The disease is one with which we were quite familiar before the operation was introduced and we can recall what the results were. It was always a more severe disease in the young people. Over a considerable number of years before the introduction of prostigmin I never saw a patient under the age of 25 survive for more than twelve months, and it was rare for them to do anything other than go steadily downhill. It is precisely with these young patients that Mr. Keynes reports his best results. Whether the thymus has anything directly to do with myasthenia or not, for these patients the operation does something which is dramatic and life-saving.

The two children who have been shown are extreme examples of this. It happened that by the kindness of Dr. Wyllie I saw both of them before they were operated on—one of them was just surviving in a Drinker respirator—and making such allowances as my experience permits me to make for the possibility of remission on the point of death, I cannot believe that they would both be as they are this evening, or be here at all, if they had not had the operation. That then is my conclusion as regards the young people.

Of the older patients many, especially since the arrival of prostigmin, passed into a chronic state—sometimes a little better, sometimes a little worse. In many cases only the ocular muscles and face were affected, and in others the muscles of the jaw and throat as well. In such cases the effects of the operation are less definite. We are told that 15 patients improved greatly and 3 others moderately.

A point which should be considered is, when the improvement took place in relation to the operation. If improvement occurred at once, then we should attribute it to the operation, but if it did not occur till some months afterwards, it would be safer in assessing the results to attribute it to the effects of a remission. I feel that Mr. Keynes and Dr. Carson can afford to make that concession to the critics, because recalling my experience of this disease in the past, I can only conclude that on whatever it is based, the operation represents a great advance in the treatment of a disease which had a very high mortality.

Sir Charles Symonds said that, having examined the cases and heard Mr. Geoffrey Keynes's report, he had no doubt that thymectomy represented a very great advance in the treatment of myasthenia gravis. Spontaneous remissions were well known, and he had personal experience of several striking examples, but he was sure that the average expectation of health and life in this disease had been much less than that now offered by surgery. It would, however, be valuable to compare with Mr. Keynes's series, a series of control cases followed over a number of years in the pre-prostigmin days and in the prostigmin period, without operation. Myasthenia gravis was a rare disease, and it would be necessary in any investigation of this sort to pool the experience of neurologists.

Dr. L. P. E. Laurent: Mr. Keynes's patients certainly show some very remarkable examples of complete remission of symptoms, but my experience of myasthenia gravis in the past eighteen years, extending to some 65 cases, has led me to believe that the

prognosis is much better than is generally thought. For instance, of 16 cases who have been followed up by Dr. Mary Walker and myself for more than ten years, 13 are alive to-day. A patient who was in the National Hospital in 1912 with severe symptoms which lasted some seven years, lives to-day at Alton, Hants, where he has worked as a farm labourer for the past thirty years without relapse. Another remarkable patient was a Danish woman who had two acute episodes with respiratory crises lasting several months, and who had shown no trace of myasthenia for eight years when I last saw her.

It seems to me that Dr. Mary Walker's experiment in which she showed that release of a cuff round the arm after exercising the muscles of the forearm was followed by a rapid ptosis, requires some explanation in any theory of the causation of myasthenic symptoms. Any thymic theory must be out of keeping with this experiment.

It is disappointing that the only good prognostic factor after thymectomy should be the short duration of symptoms. The best remission in myasthenia always occurs early, and therefore the early case is always the one most likely to show a good remission even without treatment.

I have recently seen a patient belonging to this present series, a woman of 39 who did not improve after thymectomy. She is certainly suffering from muscular dystrophy, and it would therefore be interesting to know whether her thymus showed any of the slight changes which Dr. Collins has seen in some of the cases of myasthenia.

Dr. P. H. Sandifer: I should like to ask Mr. Keynes how often, in his considerable experience, he has removed thymuses from myasthenics previously treated by radiotherapy; secondly, what was the histological appearance of thymuses previously irradiated; and thirdly, if and when characteristic histological changes were witnessed, whether he noted any relationship between these changes and the dose of X-rays.

My reason for asking this question is that at one time I had under my care a myasthenic patient of Dr. Douglas McAlpine who improved enormously after a course of radiotherapy. Miss Ross gave her, at Mount Vernon Hospital, Northwood, a dose to the thymus of 1,330 r, over nine days. Seven months later thymectomy was performed with still further improvement which has not, however, remained at the previous high level.

At operation an atrophic thymus weighing 8 grammes was removed and the sections from the gland showed only a few patches of active gland tissue, the rest being pink, amorphous material replacing thymic tissue.

I think it is important to know whether it is possible to produce atrophy of the thymus by radiotherapy and, if so, what dose is necessary. Doses much larger than the 1,330 r received by this patient have been given. One patient I referred to Miss Ross received 3,743 r over twenty-one days she does not now need to take prostigmin. Another patient treated by Professor Windeyer at Middlesex Hospital by radiotherapy does not now take prostigmin and another is reducing the dose of prostigmin while at the same time becoming capable of greater exertion. Other patients treated with comparable doses of X-rays, on the other hand, have improved little or not at all.

The Influence of Wave-lengths on Certain Lesions Produced by the Irradiation of Mice

By A. LACASSAGNE

(Institut du Radium, Paris)

PRELIMINARY CONSIDERATIONS

I SHALL be dealing with the results of various experiments undertaken between 1941 and 1944, some of which, having been temporarily abandoned, have not previously been described. During this period, for obvious reasons, we were obliged to reduce the size of our experimental animals: rabbits, formerly in general use, had to be replaced by mice. This reduction in the size of the subject necessitated a modification of the means employed. In order to adapt the power used to the much lower penetration required when dealing with these very small animals, soft rays—which, indeed, turned out to be suitable for many other reasons—had to be used.

I propose to describe successively lesions caused by (a) K radiation of molybdenum; (b) ultraviolet rays; (c) L radiation of silver.

(a) Irradiation by K Radiation of Molybdenum.

The following experiments, undertaken in collaboration with A. Chamorro, were intended to establish the dose required to induce total sterilization of the ovaries in mice, resulting in complete cessation of cyclic vaginal activity and sexual activity.¹

Female mice two months old were treated with unfiltered rays from a molybdenum anode—effective wave-length 0.95 Å. With a tension of 35 kV., an intensity of 15 mA., and a focal distance of 12 cm., a dose of 3,000 r per minute was measured on the surface of the skin. The mice, anaesthetized with ether, were fixed, ventral surface downwards, on a board. Their bodies were protected by sheets of lead, having perforations in the lumbar region 1 cm. square, each of which corresponded to the site of an ovary.

In this way four groups of mice received respective doses of 3,000, 4,500, 6,000 and 9,000 r in the ovarian region. Two of the 6,000 r group and all the 9,000 r group died less than six weeks later as a result of the experiment. I shall not refer to the purely physiological changes observed in the survivors; I shall briefly indicate the effects of the treatment on the cutaneous tissues, and describe in greater detail the histological changes occurring in some cases in the ovaries and kidneys.

(1) *Cutaneous reactions.*—The only phenomenon which called for notice on examining the skin during the weeks following irradiation was the loss of hair over the area exposed to the rays. This occurred on approximately the same date—about the twentieth day—regardless of the dose. In no case was there any sign of ulceration. There was a sparse growth of new hair in the case of animals receiving doses of 3,000 and 4,500 r, and an extremely feeble scattered growth in those receiving 6,000 r. The depilation remained quite obvious. It was sometimes accompanied, in the case of strong doses, by slight

¹In the series of results published by Parkes, and by Brambell and Parkes (*Proc. Roy. Soc. B*, 1927-28) this "Roentgen castration," achieved long before in the case of rabbits, was not attained.

prognosis is much better than is generally thought. For instance, of 16 cases who have been followed up by Dr. Mary Walker and myself for more than ten years, 13 are alive to-day. A patient who was in the National Hospital in 1912 with severe symptoms which lasted some seven years, lives to-day at Alton, Hants, where he has worked as a farm labourer for the past thirty years without relapse. Another remarkable patient was a Danish woman who had two acute episodes with respiratory crises lasting several months, and who had shown no trace of myasthenia for eight years when I last saw her.

It seems to me that Dr. Mary Walker's experiment in which she showed that release of a cuff round the arm after exercising the muscles of the forearm was followed by a rapid ptosis, requires some explanation in any theory of the causation of myasthenic symptoms. Any thymic theory must be out of keeping with this experiment.

It is disappointing that the only good prognostic factor after thymectomy should be the short duration of symptoms. The best remission in myasthenia always occurs early, and therefore the early case is always the one most likely to show a good remission even without treatment.

I have recently seen a patient belonging to this present series, a woman of 39 who did not improve after thymectomy. She is certainly suffering from muscular dystrophy, and it would therefore be interesting to know whether her thymus showed any of the slight changes which Dr. Collins has seen in some of the cases of myasthenia.

Dr. P. H. Sandifer: I should like to ask Mr. Keynes how often, in his considerable experience, he has removed thymuses from myasthenics previously treated by radiotherapy; secondly, what was the histological appearance of thymuses previously irradiated; and thirdly, if and when characteristic histological changes were witnessed, whether he noted any relationship between these changes and the dose of X-rays.

My reason for asking this question is that at one time I had under my care a myasthenic patient of Dr. Douglas McAlpine who improved enormously after a course of radiotherapy. Miss Ross gave her, at Mount Vernon Hospital, Northwood, a dose to the thymus of 1,330 r, over nine days. Seven months later thymectomy was performed with still further improvement which has not, however, remained at the previous high level.

At operation an atrophic thymus weighing 8 grammes was removed and the sections from the gland showed only a few patches of active gland tissue, the rest being pink, amorphous material replacing thymic tissue.

I think it is important to know whether it is possible to produce atrophy of the thymus by radiotherapy and, if so, what dose is necessary. Doses much larger than the 1,330 r received by this patient have been given. One patient I referred to Miss Ross received 3,743 r over twenty-one days she does not now need to take *prostigmin*. Another patient treated by Professor Windeyer at Middlesex Hospital by radiotherapy does not now take *prostigmin* and another is reducing the dose of *prostigmin* while at the same time becoming capable of greater exertion. Other patients treated with comparable doses of X-rays, on the other hand, have improved little or not at all.

sclerosis of the cellular-fatty tissue, and even by a slight degree of atrophy of the cutaneous muscle.

(2) *Total sterilization of the ovary.*—The result which we were out to attain was realized in only a small proportion of cases. Eleven mice survived for more than three months. In only three of these cases—two irradiated with 4,500 and one with 6,000 r—was there total atrophy of both ovaries, and consequently of the horns of the uterus and the mammary organs, as well as permanent mucification of the vaginal epithelium. In all, out of a total of sixteen mice—the eleven already referred to and five others which survived long enough to make a histological examination of the ovaries worth while—two only, after a dose of 3,000 r, showed total atrophy, and then of only one gland (fig. 1).

These results seem to show that the chief difficulty in such experiments is to locate the ovaries exactly. In attempting to confine the irradiation to a very restricted field, so as to avoid too heavy a mortality, we rarely succeeded in administering the precise dose required to both ovaries, either because our calculation of the site for irradiation was originally incorrect, or because the subject moved during the course of the experiment. One proof of this is that three mice were subsequently found to be gravid; in two cases, killed before expulsion, the fetuses were found to occupy only one horn of the uterus. Nevertheless, the results so far obtained are sufficient to show that from 3,000 r upwards it is possible to induce total sterilization of the mouse ovary, together with the cessation of all physiological activity—in other words, complete castration.

Histological examination.—The study by successive sections of an ovary sterilized by a dose of 3,000 r, undertaken sixty-four days later, showed considerable atrophy of the organ, which was reduced to a little tongue about a millimetre long by half a millimetre wide, resting on a muscular plane, the medullary surface serving as a hilum, and covered on the other surface and on the edges by the ovarian epithelium, which had not suffered the same retrogression as the rest of the organ, its cells being more closely knit and higher, and definitely prismatic or cylindrical in shape (fig. 2). The parenchyma showed (a) a cortical substance, consisting of a much reduced stroma of small cells, the nucleus highly chromatic, displaying a wheelspoke formation, indicating the presence of atrophied interstitial cells; (b) a vascular-connective medullary substance. Not an intact follicle of any kind, no oocytes, no anovular formations, no tubular invagination of the epithelium was found. On the other hand, the parenchyma was riddled, as far as the medullary zone, with cavities, apparently of a cystic nature, containing structureless debris, strongly acid-fast, sometimes resembling a more or less wrinkled membrane: these were the remains, as yet unabsorbed, of large follicles which had degenerated as a result of the irradiation.

A similar histological examination was made of three ovaries, irradiated with 3,000 or 4,500 r, and opened from 106 to 149 days later. They presented the same appearance. There was some diminution in the number of recognizable interstitial cells; there still remained a large number of cavities indicating degenerated large follicles. There was no sign of repair or regeneration originating in the ovarian epithelium.

Finally, the ovaries of a mouse which had survived and remained sterile for 583 days after irradiation with 6,000 r showed an extreme degree of atrophy. Only the ovarian epithelium retained its characteristics. The internal structure of the organ was unrecognizable; cortical and medullary substance were indistinguishable; all traces of interstitial cells had disappeared. Moreover, there was now no trace of the cystic remains of the old unruptured follicles. The stump of the vascular-connective process showed what appeared to be several macrophages, containing a little pigment (fig. 3).

(3) *Atrophic lesions of the kidney.*—Our attention was attracted by a curious radiolesion, which, as far as I know, has not previously been described, and which sensibly modifies the classical theory as to the sensitivity of the kidney to irradiation. Possibly it may have escaped notice owing to the fact that it takes some time to establish itself. It was observed only in mice which had survived for longer than 300 days. There were four of these, three having received 3,000 and the fourth 6,000 r. All four presented the same changes.

It must be remembered that the ovary of the mouse is related to the inferior pole of the kidney; its irradiation accordingly involves a more or less important segment of the latter organ. On examining the body of a mouse irradiated only 340 days earlier, there was a marked deformation of the right kidney, which had become pear-shaped as a result of the atrophy of its lower half. In three other cases, where the subjects had survived for 570, 583 and 616 days respectively, the lesion was bilateral, being more marked sometimes on the right, sometimes on the left.

it. I need not describe the cytolysis which may be observed by the end of the first twenty-four hours, and attacks simultaneously the epithelial cells of the epidermis and its invaginations, the endothelium of the capillaries and the connective cells of the dermis (fig. 5).

On the other hand, the process of repair is equally early and lively. As early as the third day, a layer of epithelial cells begins to migrate from the edges of the peripheral epidermis, producing a wedge-shaped penetration into the dead tissue; in the same way, from the fourth day onwards, mobile connective elements and new capillaries penetrate the dermis from all sides, and from the whole depth of the cutaneous muscle. By the seventh day, a new epidermis has grown under the disc of dead tissue which is about to separate in the form of a scab.

Moreover, in mice only a few days old, the healed epidermis retains the power to regenerate the sebaceous glands of the hair follicles. It develops on its deep surface buds which penetrate the dermis. But at this point most of them find themselves up against thick scar tissue, and so degenerate. Only a small proportion succeed in reaching the vascular plane formed under the cutaneous muscle and so become differentiated as sebaceous glands and hair follicles. This explains why the area once irradiated remains clearly recognizable, bearing only a few scattered hairs, and showing a slight depression owing to loss of substance and the atrophy suffered by the dermis (fig. 6).

(2) *In the adult mouse.*—As far as the absorption of the rays is concerned, the result seems to be identical with that in the newborn mouse. Necrosis is rapid, and attains the same depth of approximately 150 μ . But the much thicker skin of the adult mouse means that the rays work in different conditions, and so necrosis attacks only the epidermis and that part of the dermis immediately underlying it. Consequently, the sebaceous hair follicles suffer a kind of necrotic amputation below the neck, and only the upper half is destroyed (fig. 7).

As a result, the process of regeneration of the epidermis, which here also starts very early, is effected not only from the edges of the irradiated area, but also from the healthy stump of the epidermic sheaths of the hair. There is no formation of new follicles, but the preservation of a certain number of old ones—though many degenerate as a result of the sclerosis of the dermis in which they are rooted. Finally, after about twelve days, there is a cicatrix recognizable as a very slightly atrophied zone, sparsely sown with hair, closely resembling what I have described in the case of the newborn mice, but resulting from a somewhat different repair process.

(c) *Irradiation with L. Radiation of Silver.*

The experiments conducted with the collaboration of R. Latarjet, have not previously been the subject of a communication. They were all concerned with newborn mice. We set ourselves to discover the dose required in order to produce a destruction of the epidermis equal to that described above, and to compare the histolytic process and that of repair in the case of ultraviolet rays and X-rays.

We used a silver anode tube, functioning at 4,500 volts and 50 milliamperes. The distance between the window of the tube and the skin was not more than 1 mm. The rays were filtered by 15 μ of aluminium which gave a wavelength of about $4\frac{1}{2}$. In these conditions the absorption of the rays at various depths, according to measurements made by my collaborators Frilley and Latarjet, was 50% at 15 μ , 60% at 30 μ , 67% at 50 μ and 75% at 120 μ . Thus, with irradiation of different wave-lengths, we approximated closely to the limits of penetration previously observed when irradiating the skin of the mouse with ultraviolet rays.

Our first experiment was designed to establish the dose administered to the skin of the dorso-lumbar region, required to produce a lesion macroscopically comparable with that obtained with 1,500 f of ultraviolet rays. Eight young mice from the same litter were each given an increasing dose with a minimum of 44 and a maximum of 2,680 ergs per square millimetre. The successive reactions were noted, and it was apparent that the scabby ulceration obtained after the administration of 500 ergs gave place, once the scab had separated, to a partially hairless zone analogous to that described above in connection with irradiation by ultraviolet rays.

This dose was administered to eleven young mice from two litters which were killed after intervals of from three hours to nineteen days in order to provide material for the histological study of the establishment of the lesion and its repair.

The reactions apparent on direct examination of the skin of the living animal were much less rapid and severe than those caused by ultraviolet rays. There was erythema

A histological examination showed an unexpected feature of the area affected by the rays. The lesion did not involve the whole thickness of the organ, but decreased progressively. From the dorsal surface, where the rays had entered, it extended to a greater or lesser degree, actually, in some cases, reducing the transverse diameter of the kidney—which, in an adult mouse, is about five or six millimetres—by more than half. Under the thickened capsule were found, first a mass of malpighian bodies, almost in a state of fusion, among which all trace of the convoluted tubules had vanished. These corpuscles were in three, six or eight layers, according to the depth of the penetration. Nevertheless, among those which lay deepest the debris of uriniferous tubules could be seen:—isolated epithelial cells, or masses consisting of a few cells or hyaline casts—even tubules which had escaped necrosis sufficiently to be still recognizable as such. On the frontier between the lesion and the healthy renal parenchyma there was a definite and organized infiltration of leucocytes, sometimes forming quite a mass of lymphatic tissue surrounding the vessels.

But what is even more remarkable is the appearance of the malpighian bodies themselves. Whereas the epithelial covering of the uriniferous tubules was completely destroyed, the glomeruli were not affected and, as a rule, appeared to be intact. They were certainly still capable of functioning, for the capillaries contained red corpuscles, and the cavity was full of an acellular liquid, possibly slightly albuminous, since there was sometimes a little coagulum. But as this infiltrating liquid could find no way of escape, it distended the capsule, now reduced to a thin connective membrane. Each corpuscular cavity was thus dilated until its volume was at least doubled; the glomerular tuft being pushed back towards the vascular pole. In this state the irradiated area assumed somewhat the appearance of a polycystic kidney (fig. 4).

It would be interesting to establish, by experiments undertaken at an earlier stage, the successive stages of such lesions. This was not done. But the results described provide a conclusive argument in the age-long controversy as to whether parenchymatous lesions are the cause or the result of changes in the vessels. The uriniferous tubules here revealed quite clearly the extreme sensitivity to irradiation of the epithelial cells, presenting a remarkable contrast with the apparent integrity of the vascular formations.

(b) *Irradiation with Ultraviolet Rays.*

The various experiments now to be described were the subject of papers published by Lacassagne and Latarjet, in 1943 and 1945.¹ They allowed us to study the effects upon the skin, going as far as almost complete necrosis in newborn mice, only partial in adults, produced by strong doses of ultraviolet rays; and to note the process of repair.

The skin was irradiated in the dorso-lumbar region. The mice were protected from heat, and enclosed in a sleeve with an opening defining the required section of skin, usually bald, in newborn mice, and epilated a week earlier in adults. We used the total radiation of a Philips' Biosol mercury vapour lamp, calibrated in finsens per minute, 103.5 volts; 7.75 ampères, giving 300 f per minute. In these conditions we found that in mice one or two days old, the threshold value for erythema was 200 f, for true erythema 600 f, for desquamation 800 f; exudative epidermatitis was reached at 1,000 f, and necrotic dermatitis at 1,500 f, 90,000 ergs per square millimetre.

Let me describe the effect of this dose of 1,500 f upon an area measuring 6 by 5 millimetres in newborn mice, or 1 square centimetre in the adults.

(1) *In newborn mice* the irradiation in these conditions provokes, in the hours following administration, an enormous reaction producing œdema extending beyond the irradiated area, and accompanied by intense erythema lasting for five or six days. Then the affected area dries up and becomes covered with a scab, which separates after a week, revealing an epidermis, bald at first, but quite shortly to be sprinkled with scattered hairs.

Microscopical examination of the lesion thus produced in the skin of mice a day or two old reveals two things.

First there is a rapid local necrosis involving every variety of cell.

Secondly, this destruction is not deep-seated, but penetrates only to about 150 μ . Now in the case of these small immature animals the affected area includes the whole of the epidermis and the entire dermis, with the bulbs of the developing hair follicles buried in it. The destructive process reaches the cutaneous muscle without going beyond

¹C. R. Soc. de Biol. (1943), 147, 413 and 435; C. R. Soc. de Biol. (1945), 139, 4.

it. I need not describe the cytolysis which may be observed by the end of the first twenty-four hours, and attacks simultaneously the epithelial cells of the epidermis and its invaginations, the endothelium of the capillaries and the connective cells of the dermis (fig. 5).

On the other hand, the process of repair is equally early and lively. As early as the third day, a layer of epithelial cells begins to migrate from the edges of the peripheral epidermis, producing a wedge-shaped penetration into the dead tissue; in the same way, from the fourth day onwards, mobile connective elements and new capillaries penetrate the dermis from all sides, and from the whole depth of the cutaneous muscle. By the seventh day, a new epidermis has grown under the disc of dead tissue which is about to separate in the form of a scab.

Moreover, in mice only a few days old, the healed epidermis retains the power to regenerate the sebaceous glands of the hair follicles. It develops on its deep surface buds which penetrate the dermis. But at this point most of them find themselves up against thick scar tissue, and so degenerate. Only a small proportion succeed in reaching the vascular plane formed under the cutaneous muscle and so become differentiated as sebaceous glands and hair follicles. This explains why the area once irradiated remains clearly recognizable, bearing only a few scattered hairs, and showing a slight depression owing to loss of substance and the atrophy suffered by the dermis (fig. 6).

(2) *In the adult mouse.*—As far as the absorption of the rays is concerned, the result seems to be identical with that in the newborn mouse. Necrosis is rapid, and attains the same depth of approximately $150\ \mu$. But the much thicker skin of the adult mouse means that the rays work in different conditions, and so necrosis attacks only the epidermis and that part of the dermis immediately underlying it. Consequently, the sebaceous hair follicles suffer a kind of necrotic amputation below the neck, and only the upper half is destroyed (fig. 7).

As a result, the process of regeneration of the epidermis, which here also starts very early, is effected not only from the edges of the irradiated area, but also from the healthy stump of the epidermic sheaths of the hair. There is no formation of new follicles, but the preservation of a certain number of old ones—though many degenerate as a result of the sclerosis of the dermis in which they are rooted. Finally, after about twelve days, there is a cicatrix recognizable as a very slightly atrophied zone, sparsely sown with hair, closely resembling what I have described in the case of the newborn mice, but resulting from a somewhat different repair process.

(c) *Irradiation with L Radiation of Silver.*

The experiments conducted with the collaboration of R. Latarjet, have not previously been the subject of a communication. They were all concerned with newborn mice. We set ourselves to discover the dose required in order to produce a destruction of the epidermis equal to that described above, and to compare the histolytic process and that of repair in the case of ultraviolet rays and X-rays.

We used a silver anode tube, functioning at 4,500 volts and 50 milliamperes. The distance between the window of the tube and the skin was not more than 1 mm. The rays were filtered by $15\ \mu$ of aluminium which gave a wavelength of about 4Å . In these conditions the absorption of the rays at various depths, according to measurements made by my collaborators Frilley and Latarjet, was 50% at $15\ \mu$, 60% at $30\ \mu$, 67% at $50\ \mu$ and 75% at $120\ \mu$. Thus, with irradiation of different wave-lengths, we approximated closely to the limits of penetration previously observed when irradiating the skin of the mouse with ultraviolet rays.

Our first experiment was designed to establish the dose administered to the skin of the dorso-lumbar region, required to produce a lesion macroscopically comparable with that obtained with 1,500 f of ultraviolet rays. Eight young mice from the same litter were each given an increasing dose with a minimum of 44 and a maximum of 2,680 ergs per square millimetre. The successive reactions were noted, and it was apparent that the scabby ulceration obtained after the administration of 500 ergs gave place, once the scab had separated, to a partially hairless zone analogous to that described above in connection with irradiation by ultraviolet rays.

This dose was administered to eleven young mice from two litters which were killed after intervals of from three hours to nineteen days in order to provide material for the histological study of the establishment of the lesion and its repair.

The reactions apparent on direct examination of the skin of the living animal were much less rapid and severe than those caused by ultraviolet rays. There was erythema

on the third day, followed by pigmentation. On the eighth day, the irradiated area, still hairless, was the site of severe desquamation followed by superficial ulceration forming a scab on about the twelfth day, which separated on the sixteenth day exposing a red, smooth and hairless epidermis. The regrowth of hair began on the thirtieth day.

Nevertheless, histological study showed that cellular changes, although they began to declare themselves very early, affected only certain elements extremely sensitive to radiation. After twenty-four hours, this selective action of the rays was confined to the invaginations of the epidermis which were to constitute the hair follicles. Many of these cells already showed signs of advanced degeneration, whereas the epidermis, properly so-called, manifested no more than a simple cellular swelling and the disappearance of mitoses, and the dermis showed no reaction of the connective tissues. On the third day the epithelial lesions had become considerable; there was partial destruction of the follicle buds; the cells of the covering epidermis showed many anomalies and a general maturation of its elements gave the appearance of hyperkeratosis. Nevertheless there was no œdema of the connective tissue, simply a little diapedesis of leucocytes round the capillaries (fig. 8). The cornification of the whole epidermis and the degeneration of the follicular buds were very advanced on the fifth day, whereas there was only a slight infiltration of leucocytes in the immediately underlying dermis, and the deep layers were apparently unaffected. On the ninth day the progressive degeneration of the whole epidermis was complete; those parts which had cornified formed a scab beneath which a fresh layer of epidermis was beginning to creep in from the edges of the ulcerated area. There was marked inflammation of the dermis, with a strong infiltration of leucocytes, but no degeneration of the fixed cells (fig. 9). On the eleventh day, under the scab just about to separate, a thin, smooth epidermis had formed, which showed a few sparse invaginations.

This description of the histological process of degeneration of the epidermis by selective action on the cells of the germinative process agrees with the well-known account of epidermitis due to irradiation published by Regaud and Nogier; it is typical of the effects of X-rays in the shorter wave-lengths. On the other hand it differs completely from the diffuse necrosis of the epidermis caused by ultraviolet rays.

It might be supposed that this difference was due to the considerable inequality of energy applied in the two groups of experiments—9,000 ergs per square millimetre in the case of ultraviolet rays as against 500 for L radiations of silver,¹ in spite of the fact that these two doses resulted in an equal degree of macroscopic destruction.

Since in our search for the histological picture of skin lesions which should be comparable in one and the other of two types of radiation of different wave-lengths, an increase in the dose of X-rays would have been impossible, as it would have meant impossibly lengthy irradiation, the dose of ultraviolet rays had to be reduced.

Histological lesions produced by doses of 500 to 1,500 finsens.—Ten young mice from two litters of the same stock, two days old, were irradiated with a dose starting at 500 finsens, or 30,000 ergs per square millimetre, and increasing at each administration by 100 finsens. All the animals were killed three days later, just when the epidermic lesions would present their most characteristic appearance.

Even with a dose of 500 f, which, as mentioned above, caused only slight erythema, with no more serious desquamation than was found in the rest of the skin, and no loss of hair, the histological lesions were already obvious. But, unlike those caused by a dose of 1,500 f, they involved only a shallow depth of cells.

First, there was a squamous layer, thicker than the neighbouring integument, partly detached, and separated from the epidermis by a space containing a certain number of leucocytes, which had reached it by diapedesis through the remains of the epidermis, which, in fact, was not wholly destroyed. Here we recognized a picture resembling that described above in connexion with irradiation by 1,500 f of the thicker skin of the adult mouse: a continuous epidermis, forming a unicellular film in some parts, multistratified in others, including between the layers the follicular invaginations whose cellular elements were not attacked. The changes in the dermis consisted simply in the mobilization of the leucocytes; beneath the epidermis we found only a small number of cells which had undergone cytolysis (connective cells or leucocytes?). But there was obvious dilatation of the capillaries, the endothelium of which appeared to be intact; and there was a characteristic œdematous condition of the loose cellular tissue

¹It is important to remember that comparison of the results of irradiation by X-rays and ultraviolet rays on isolated cells (bacteria or ferments) has established that the same degree of lesion is obtained from the absorption of 200 times less energy in the case of X-rays than in that of ultraviolet rays (Latarjet, *Ann. Inst. Pasteur* (1913), 69, 205).

FIG. 6.—Irradiated skin of newborn mouse (ultraviolet radiation; dose 1,600 r) after 2 days. On left, irradiated segment; complete necrosis extending as far as the cutaneous muscle. On right, protected segment. $\times 25$.

under the cutaneous layer. Moreover, the whole irradiated area was retarded in growth compared with the neighbouring areas. The dermis was thinner and the hair thinner and more sparse (fig. 10).

Here again there were none of the characteristics of an X-ray lesion of the epidermis, nor were there any after stronger doses; in fact, all that happened was that as the dose was increased the extension in depth of the diffuse necrosis increased in proportion. At 1,000 and 1,200 f this reached in the dermis about half the space between the epidermis and the cutaneous muscle.

We are thus forced to conclude that the destruction of the epidermis by ultraviolet rays and by X-rays is attained by two distinct histological processes. With ultraviolet rays there is no sign of selective radiosensitivity, but a kind of "all or nothing" effect, with necrosis of the cellular layers one after another, according as the increased dose

FIG. 10.—Irradiated skin of newborn mouse (ultraviolet radiation; dose 500 f) after 3 days. $\times 100$.

achieves the threshold value for cell destruction at greater and greater depth. X-rays, on the other hand, act selectively on the cells of the germinative layers of all the epithelial tissue, including the deep invaginations of the growing follicles.

SUMMARY

In conclusion, irradiation of a limited area of the dorsal lumbar region in mice was carried out with three types of radiation of different wave-lengths: K radiation of molybdenum, L radiation of silver and ultraviolet rays. Naturally deep-seated histological lesions, apart from those of the skin, were observed only in the first case.

(1) With a dose of K radiation of molybdenum, 3,000 r on the surface of the skin (corresponding to an incident energy of 760 ergs per square mm.) the only effect produced on the skin of the adult mouse is a clearly defined loss of hair, effected by selection, without ulceration of any kind. On the other hand, the ovary and parts of the kidney, situated about 5 mm. below the surface, are clearly and seriously affected. There is complete sterilization of the ovary and destruction of the uriniferous tubules, the glomeruli being unaffected. The fact that the intensity of the rays at a depth of 4 mm. is only about 25% of that on the surface makes it very clear that the epithelial tissues of the ovary and kidney are far more sensitive to irradiation than those of the epidermis.

(2) With L radiation of silver, a dose producing an incident energy of 500 ergs per square mm. applied to the skin of a newborn mouse causes destruction of the epidermis by a histological process of selective radio-epidermitis. The effect on the skin is thus much more severe than that caused by a stronger dose of K radiation of molybdenum. This difference is easily explained by the fact that the absorption of the rays by the skin is proportionately much higher in the case of the longer wave-length.

(3) Two radiations of different wave-lengths—L radiation of silver and ultraviolet rays—absorbed in depth in comparable proportions—both cause destruction of the skin of the newborn mouse, but the histological process in the two cases is totally different.

DISCUSSION ON THE CHEMOTHERAPY OF MENINGITIS SECONDARY TO INFECTION OF THE EAR AND NASAL SINUSES

OPENERS:

Honor V. Smith, M.B., B.Sc.Lond.

F. Schiller, M.D.Prague.

Hugh Cairns, D.M.Oxford, B.S.Adelaide, F.R.C.S.

(Nuffield Department of Surgery, Oxford)

OTOGENIC meningitis and meningitis secondary to infection of the nasal sinuses have much in common. In both the bacteriology is similar, in both the meningitis may be complicated by abscess formation and in both the problems of treatment are in many respects the same. We therefore propose to discuss these two groups of cases together. We also include certain cases where the meningitis arose not from a frank sinusitis but as a result of a fracture involving the nasal sinuses (Table I).

TABLE I.—A SERIES OF 37 CASES SECONDARY TO INFECTION OF THE EAR AND NASAL SINUSES ANALYSED ACCORDING TO AETIOLOGY AND BACTERIOLOGY.

Source of infection	Pneumococci	Streptococci	Staphylococci	Mixed	<i>H. influenzae</i>	Total
Otitis	13	4	1	2*	1	21
Sinusitis	6	3	0	0	0	9
Fracture through sinuses	6	1	0	0	0	7
Total	25	8	1	2	1	37

* (i) Pneumococci + *Staph. aureus*; (ii) Streptococci + *Staph. aureus*.

Some of our patients were referred to us directly as cases of meningitis. Often this was because the bacteriologist who examined the C.S.F. identified Gram-positive organisms and made it his business immediately to get in touch with the clinician in charge of the case and urge treatment with penicillin. The site of the primary focus of infection was often discovered only after careful assessment of the history and clinical and radiographic examinations. Others were first admitted to hospital, either at Oxford or elsewhere, for treatment of the nose or throat. In these the meningitis usually developed while they were under observation. In those cases where the meningitis followed a fracture through the sinuses, some of the patients were admitted to hospital on account of their head injury, while in others the head injury preceded the meningitis by a variable interval and was only discovered by a study of the history.

From the practical point of view cases with this aetiology fall into three main groups: (1) Those in which no organisms are recovered from the C.S.F.; (2) those due to organisms which are either relatively or totally resistant to penicillin; (3) those due to infection by penicillin-sensitive organisms.

The first group includes those cases of relatively low-grade infection sometimes called "sterile" meningitis and also cases of intracranial abscess where bursts of mild meningitis develop during the course of the illness. These cases usually respond well to sulphonamides and unless an abscess is present no other form of chemotherapy may be needed. The patients must, however, be carefully watched and their progress checked by repeated bacteriological examination of the C.S.F., since fluid which is at first sterile may later give a positive culture (Smith *et al.*, 1946, Case 1). If the patient has received sulphadiazine before the lumbar puncture is done, cultures of the C.S.F. must be set up with para-aminobenzoic acid. They will otherwise probably be sterile when the true nature of the infection will be missed.

The second group is small but important. The predominating organisms are *H. influenzae* and *B. proteus*. Fortunately these cases are not common as the mortality in this country has been high. Occasionally influenza meningitis responds to heavy and prolonged dosage with sulphadiazine, while in America Alexander (1944) has achieved excellent results by the use of immune rabbit serum which is given in conjunction with sulphadiazine. Recently cases have been reported in which the infection has been controlled by intrathecal penicillin (Forgacs, Hutchinson and Rewell, 1945; Straker, 1945), and it appears that, at least with certain types, the resistance of *H. influenzae* to penicillin is relative rather than absolute.

We have treated one case of otogenic influenzal meningitis.

CASE I.—R.I. 25486/44.

A baby of 8 months was one day noticed to have a thick purulent discharge coming from his right ear. He did not seem unwell at that time but five days later the left ear also began to discharge. Eight days later he was admitted to the Ear, Nose and Throat Department of the Radcliffe Infirmary, and the following day a bilateral Schwartz mastoidectomy was performed. The right mastoid contained a fair amount of mucopus, but the left only showed some injection. Following operation the condition of his ears was uniformly satisfactory, but his temperature rose, and he was given sulphathiazole (3 grammes daily). For the next ten days his temperature was maintained at about 102° F. without the development of any physical signs, but on the eleventh day he developed a squint and on the twelfth day was found to have considerable neck stiffness. A lumbar puncture revealed a cloudy fluid but no organisms were seen on the direct film, and it was not until four days later that the organism grown on culture was identified as *H. influenzae*.

During these four days, treatment with intramuscular and intrathecal penicillin was given in view of the previous lack of improvement on sulphathiazole. There was no clinical improvement throughout this period.

When the organism was reported as insensitive to penicillin, sulphadiazine (3 grammes daily) was begun, and the penicillin discontinued. Thereafter the child slowly improved, but one attempt to reduce the dose of sulphadiazine, and another to discontinue the drug after three weeks, were quickly followed by clinical and bacteriological relapse. Finally the child made a complete recovery after having received sulphadiazine for seven weeks. At no time were any signs of drug intolerance detected.

The third group is the largest and most important. The commonest organisms are pneumococci and streptococci, both hæmolytic and anaerobic. Staphylococci are much rarer (Stewart, 1929; Weinstein, 1942). The predominance of pneumococcal over streptococcal infections in our series may be due to the fact that we were making a special study of pneumococcal meningitis at the time when these cases were treated; on the other hand, before the days of effective chemotherapy, many cases of pneumococcal meningitis must have died before admission to hospital. Our experience is still very limited, especially with streptococcal and staphylococcal meningitis, but we will produce evidence that the nature of the organisms is of considerable practical importance. The bacteriology and aetiology of cases is shown in Table I. We have omitted those cases where the nature of the organisms was not proved by culture.

Except for meningococcal meningitis, which seldom requires treatment with penicillin, the treatment of meningitis due to penicillin-sensitive organisms is essentially the same whatever the infecting organism. This may conveniently be considered under three headings: (1) Treatment of the leptomeningitis; (2) detection and treatment of a complicating intracranial abscess; (3) treatment of the primary focus of infection.

(1) Treatment of Leptomeningitis

We have recently described our methods in full (Smith *et al.*, 1946) but the most important points in what we consider the basic treatment of meningitis may be recapitulated. As a routine we use both intrathecal and systemic penicillin with sulphadiazine by mouth. Penicillin for intrathecal use is made up in a solution of 2,000 u./c.c. and given in doses of from 8,000 to 10,000 units. During the first thirty-six to forty-eight hours injections should be given every twelve hours but thereafter daily injections are usually sufficient. The efficacy of dosage and treatment should be checked by daily bacteriological examination of the C.S.F. and estimation of its penicillin content, which, in a few patients, reveals that penicillin escapes unusually quickly from the C.S.F. In these the frequency of injections can then be increased so that a bacteriostatic concentration is constantly maintained.

The easiest and safest way of giving the intrathecal injections is by lumbar puncture. About 6 c.c. of C.S.F. is withdrawn for examination, and the penicillin then slowly injected. The injection should be frequently interrupted by aspiration of C.S.F. This insures that the needle is correctly placed and also dilutes and warms the solution. The lumbar route is only effective when the cerebrospinal pathways are patent. The earliest sign of their occlusion is a slowing in the flow of C.S.F. and difficulty in aspiration during the injection. This observation must be checked by repeating the tap in a higher space and using a wide-bore needle since if it is confirmed it is an absolute indication for giving penicillin either by the cisternal or, preferably, by the ventricular route.

The intrathecal penicillin is supplemented by the oral administration of sulphonamides. Sulphadiazine, in doses of 12 grammes in twenty-four hours, is at present the preparation of choice because it diffuses freely from the blood into the C.S.F. It therefore reaches all parts of the cerebrospinal pathways including any loculi that may be inaccessible to the penicillin. It is given to suppress the virulence of the infection and thus to help maintain the patency of the cerebrospinal pathways. In any case of

meningitis treatment with sulphadiazine should be begun immediately as this will tide the patient over the interval that may elapse before treatment with penicillin is started. Systemic penicillin is given either by continuous intramuscular drip or by intermittent three-hourly injections. The minimal daily dose is 120,000 u. in twenty-four hours, but in certain cases, for example in the presence of a frank septicæmia, this should be increased as much as 320,000 in twenty-four hours. We have no evidence that systemic penicillin alone can cure meningitis and its chief value lies in the control of the primary focus of infection and of a complicating septicæmia or pyæmia.

The intrathecal penicillin must be continued for at least five days, for although clinical and bacteriological improvement is usually obvious after three days, the cerebrospinal fluid has probably not been completely sterilized. 10 of the 37 patients in this series relapsed even after a full intrathecal course, and from our experience, if less than five days' treatment is given the proportion that relapse increases. There is also the danger that the relapse may be fatal and uncontrollable. Relapse is most common within the first forty-eight hours after the last intrathecal injection but may occur even while the patient is receiving daily lumbar injections. When this happens, either the solution in use has lost its activity, or penicillin is not reaching the site of infection, or is escaping from the theca unusually rapidly. Two of our patients relapsed even when convalescence seemed assured, and in two others isolated positive cultures from the C.S.F. were obtained without any concomitant clinical disturbance. Sulphadiazine should be given during the period in which the intrathecal penicillin is withdrawn as it provides a safeguard against uncontrollable relapse.

In a relapse, rise in temperature and recrudescence of headache and malaise precede the reappearance of cells and organisms in the C.S.F. by as much as twenty-four hours. The treatment of relapse does not differ from that of the initial attack and in our experience the prognosis as regards life and functional recovery is not altered, provided that each relapse is promptly recognized and treated. We would emphasize the need for vigilance and persistence in treating the severe relapsing case, as a complete cure can be obtained even when the illness lasts over three months.

Relapse may be due to inadequate treatment or to reinfection of the meninges either from the primary focus or from a small intrathecal fibrino-purulent collection. In otogenic cases, is relapse an indication for opening the mastoid? In only one of our cases did this prove necessary.

CASE II.—R.I. 5657/44. *Reinfection from the primary focus* (Smith *et al.*, 1946, Case VI).

A bricklayer aged 53 had a right mastoidectomy performed elsewhere following a six weeks' history of severe earache. The immediate post-operative course was smooth except that he developed a complete facial palsy, but ten days after operation he vomited, his temperature rose and he developed signs of meningitis. Lumbar puncture was performed and pneumococci (Type III) were grown on culture from the C.S.F. Treatment with sulphathiazole was at once begun and two days later he was transferred to Oxford. On admission his general condition was excellent and except for the complete right facial palsy there were no abnormal neurological signs. The mastoidectomy wound was healed and the ear was dry. Lumbar puncture revealed an almost clear C.S.F. containing only 160 cells but pneumococci were once more grown on culture.

He was then treated with intrathecal penicillin and sulphadiazine but systemic penicillin was withheld. His progress was uneventful but eight days after his last intrathecal injection he relapsed and cultures of the C.S.F. again became positive. He received a further course of intrathecal penicillin and sulphadiazine and again responded well. During convalescence he was seen by Mr. Livingstone who advised re-exploration of the mastoid and a facial nerve graft.

At operation it was found that the original operation had been incomplete. Mr. Livingstone's note states: "The antrum had never actually been reached. There were many mildly infected cells over the dura and lateral sinus. When the residual cells were removed, the sinus was found to be healthy, but in one place the dura of the middle fossa was covered with rough granulations, and these were thought to be the route of the entry of his meningeal infection". Cultures taken from this patch of granulations grew pneumococci.

The facial nerve was then freed from all residual cells and the defect repaired by a graft.

He made a permanent recovery from his meningitis and when seen a year later was free from symptoms except for a moderate right-sided deafness of middle-ear type. There was satisfactory recovery of the facial palsy.

The meninges more often become reinfected from a small intrathecal fibrino-purulent collection as in the following case:

CASE III.—*Reinfection from an intrathecal fibrino-purulent collection* (Smith *et al.*, 1946, Case VII).

A regular soldier aged 39 developed pneumococcal meningitis secondary to a right-sided otitis media. Both the initial attack and a relapse were controlled by sulphapyridine but following the second attack he died from an inhalation bronchopneumonia.

Examination of the brain revealed a collection of pus within the right auditory nerve which was continuous with a tiny abscess in the right lateral recess of the fourth ventricle (fig. 1).

FIG. 1. (Case III).—Section through medulla and cerebellum showing a fibrino-purulent collection within the sheath of the right eighth nerve continuous with a small abscess in the right lateral recess of the fourth ventricle (arrows). Such fibrino-purulent collections are probably the commonest cause of relapses.

Two of our patients whose meningitis was not primarily otogenic in origin developed a nerve type of deafness during the course of this illness. This deafness is presumably analogous to that so often seen in the past in meningococcal meningitis. In one of these patients at least, we presume the lesion was similar to that just described (fig. 1) as her illness ran a prolonged relapsing course before she ultimately recovered.

CASE IV.—R.I. 36553/44.

The patient, a housewife of 52, was admitted as an emergency on the medical side on October 24, 1945. About four weeks earlier she had caught a cold in the head and had had a slight cough but this had not interfered with her normal activities. At 8 o'clock the evening before her admission she had been visited by her daughter-in-law, who noticed no signs of ill-health, but during the night she vomited and became drowsy though restless. By the following morning she was semicomatose with neck stiffness and photophobia and with a temperature of 102°F. She was forthwith sent to hospital.

On admission she was extremely ill. She was stuporous but any attempt at examination provoked outbursts of silent struggling. Her neck was very stiff and Kernig's sign was positive. There were unequivocal signs of consolidation at the base of the right lung. Lumbar puncture showed an unusually purulent fluid (25,000 cells per c.mm.) which was swarming with pneumococci. Blood culture was also strongly positive.

Treatment was begun with intrathecal and intramuscular penicillin and sulphadiazine, but by the same evening the flow of C.S.F. was so sluggish that bifrontal burrholes were made and an intraventricular injection of penicillin given. Thereafter she steadily improved but on recovering consciousness was found to be deaf in the right ear and to have rapid poorly sustained nystagmus on looking to the left. She was also retentive of urine, and both ankle-jerks were absent.

On the eleventh day, while she was still receiving daily lumbar injections of penicillin, her temperature which had previously fallen, rose suddenly to 103°F.; she complained of headache and her neck was again stiff. Lumbar puncture the same evening showed the cells of the C.S.F. had risen from 66 to 2,500 in ten hours. The frequency of the intrathecal injections was increased, and her symptoms subsided. This was the first of seven relapses, most of which followed attempts to withhold intrathecal penicillin. No focal signs were ever detected except the right-sided deafness with nystagmus and the mild cauda equina syndrome. There was never any discharge from the ear and Mr. Macbeth, who saw the patient on several occasions, only found evidence of a transient otitis media and pan-sinusitis. He considered this part of her initial respiratory infection, and in no way responsible for the relapses and that there was therefore no indication for operation.

Unlike our other relapsing cases, in this case each relapse was milder than its predecessor and none was comparable in severity to the initial attack. The last relapse was treated with sulphamezathine only, as she had developed an intolerance to sulphadiazine (Total: sulphadiazine—136 grammes, sulphamezathine—141 grammes). Following this, recovery was permanent and she has now no residua from her long and trying illness except a moderate right-sided deafness of inner-ear type. The whole illness lasted thirteen weeks.

This case presents several points of interest:

(a) The C.S.F. at the onset of the illness was exceptionally purulent (25,000 cells/c.mm. and over 1,000 mg. of protein/c.c.). As might be expected under those conditions, a cerebrospinal block threatened to develop during the first twenty-four hours of her illness. This necessitated an intraventricular injection of penicillin. The following day the signs of incipient block had disappeared, and treatment could be continued by the lumbar route.

(b) A mild cauda equina syndrome developed during the first thirty-six hours of the illness and recovered after eight weeks. Both this and the nerve deafness were probably

due to the deposition of fibrino-purulent material round the nerve roots, as there was no correlation between the appearance and disappearance of the symptoms, and the lumbar administration of penicillin.

(c) During an illness lasting thirteen weeks the patient relapsed seven times. The earlier and more severe of these occurred while lumbar penicillin was already being given and were treated by increasing the frequency of the intrathecal injections. The later and milder relapses followed attempts to withhold intrathecal penicillin and were treated by giving a further course of injections, until the last which was successfully treated with sulphamezathine alone.

(d) Finally, this case illustrates the reversal in prognosis. Before the introduction of chemotherapy pneumococcal pneumonia complicated by septicæmia and meningitis was a lethal disease (Osler's Textbook of Medicine, 1937). Now, with penicillin and sulphonamides, full recovery can be achieved.

Precautions in use of penicillin intrathecally.—Treatment with intrathecal penicillin is not without its dangers. Of the four chief-risks three are common to all cases of meningitis while the fourth is particularly apposite in those cases which follow infection of the ear or nose.

(1) The brand of penicillin must be suitable for intrathecal use. As soon as a non-irritating preparation has been secured it should be set aside for treatment of meningitis. The best at present available is crystalline penicillin 2 (Glaxo Ltd.).

(2) Excessive dosage (40,000 u. or over at a single dose), especially when concentrated solutions are used, is capable of producing severe cerebral reactions, or, when given by lumbar puncture, damage to the cauda equina or gumming of the subarachnoid space. This last is particularly unfortunate as the most convenient route of access is then no longer available.

(3) There is a very definite risk of introducing secondary infection, especially when frequent relapses demand a large number of injections. For this reason the penicillin solution should be put in small quantities and each container only used once. A strict aseptic technique in preparation of solutions and in lumbar puncture is imperative.

(4) There is a danger in doing repeated lumbar taps on any patient with high intracranial pressure. This is probably negligible except when the meningitis is complicated by an abscess, when it is considerable. This combination of meningitis and abscess is particularly common in cases secondary to infection of the ears or nose.

Finally the closest observation and the best of nursing care are essential to success (Smith, Day and Welch, 1946). "You may hope to push the patient through, but to do so you must watch him hour by hour" (Watson, 1848).

(2) *The Detection and Treatment of a Complicating Intracranial Abscess*

Intracranial abscess and leptomeningitis are both well-known complications of otitis and sinusitis, and each has its own distinct symptomatology. Formerly we knew of cases where a cerebellar abscess was complicated by meningitis, and of others where a terminal meningitis and ventriculitis arose as a complication of abscess of the cerebral hemispheres. But since we have been treating meningitis with penicillin we have met cases in which meningitis and intracranial abscess appear to develop together. The clinical picture may then be so dominated by the signs of meningitis that the abscess is not suspected until the patient, instead of making the expected response to intrathecal penicillin, becomes moribund from raised intracranial pressure.

CASE V.—R.I. 25905/44.

The patient, a child of 12, came under our care in the early days of penicillin therapy and before we were aware of this particular combination of abscess and meningitis. Thirteen days before she had been admitted to hospital elsewhere with an acute infection of the ethmoid and sphenoidal sinuses complicated by an orbital cellulitis. She was treated with sulphathiazole in doses of 6 grammes in twenty-four hours. The infection persisted and on several occasions she vomited and complained of headache. After twelve days the ethmoid sinuses were curetted and the same evening she developed signs of meningitis. Lumbar puncture yielded a turbid fluid in which streptococci were identified and the day after operation the child was transferred to Oxford.

On admission she was delirious and extremely ill, with marked meningeal signs. There were no focal signs except right-sided proptosis. Lumbar puncture was performed. The C.S.F. was purulent and the pressure well above 300 mm. of water. 25 c.c. were withdrawn and 10,000 u. penicillin in 10 c.c. injected. After the needle was withdrawn, C.S.F. leaked through the skin puncture for several minutes in spite of firm pressure. Following lumbar puncture she rapidly grew worse and four hours later she died. Autopsy revealed a large abscess occupying the right frontal pole.

We have now seen 8 such cases of simultaneous abscess and meningitis: 4 were otogenic and 4 followed pan-sinusitis. Of the latter 4, in 3 there was a history of severe, acute sinusitis, while in the fourth the intracranial infection followed a chronic sinusitis with osteitis of the skull. In 2 there were signs of orbital cellulitis. Of the otogenic cases, in one no adequate history could be obtained; in one there was a six weeks'

history of earache, the tympanic membrane was very thick and scarred with a small anterior attic perforation and offensive purulent discharge; in the third there was a definite history of previous attacks of otitis; and in the fourth the abscess developed in a pre-existing brain fungus. It is thus possible that the abscess really predates the meningitis, although clinically they appear to develop simultaneously. The clinical detection of a complicating abscess may be extremely difficult especially as in none of our cases was any definite papilloedema detected.

In our experience the most important clue in diagnosis is the bacteriology of the infection. In our 26 cases of pneumococcal meningitis secondary to ear and nose infections, only 2 were complicated by an abscess. By contrast, among 9 cases of streptococcal meningitis an abscess was present in 5. An abscess was also found in our one case of otogenic staphylococcal meningitis. This same correlation between the bacteriology and abscess formation is seen in our cases of meningitis from other sources (fig. 2).

FIG. 2.—The incidence of a complicating intracranial abscess in the different bacteriological varieties of meningitis both in the cases forming the present series and in those of meningitis from other sources.

The type of streptococcus was not determined in every case, but there is some indication that abscess is commonest in the anaerobic streptococcal infections (Cairns and Schiller, to be published). The abscess may be intracerebral or subdural or both, but wherever it is its detection is imperative since not only does the abscess itself demand prompt surgical treatment but the meningitis must be treated by intraventricular penicillin instead of by the routine lumbar injections. Owing largely to the difficulties in diagnosis we have not yet succeeded in saving any of our otogenic cases of simultaneous meningitis and abscess. We have, however, been successful in two cases secondary to sinusitis.

CASE VI.—R.I. Illustrating the diagnostic problem of simultaneous meningitis and abscess.

A storekeeper of 47 was admitted to hospital as an emergency under the care of Mr. Livingstone. For the past fifteen years he had suffered from intermittent attacks of mild right-sided earache associated with a thin, watery discharge. Ten days before admission, the pain and otorrhoea returned, but later the discharge ceased and the pain became much worse. Twenty-four hours before admission he had a rigor and his temperature rose steeply.

On admission he was in considerable pain from his ear, his neck was a little stiff, and his temperature just over 100°F. The right external auditory meatus was filled with thick pus. Lumbar puncture revealed a cloudy fluid under a pressure of 240 mm. of water. No organisms were seen on the films and cultures were sterile. Treatment with sulphadiazine was begun, and a few hours later a right radical mastoidectomy was performed, and an extradural abscess opened. The middle fossa was widely exposed until healthy dura was found. The wound was closed with drainage.

Following operation he steadily improved and nine days later began getting up. In the early hours of the tenth day the symptoms of meningitis returned with increased severity. The C.S.F. was found to be frankly purulent and to contain a number of streptococci. By 2.30 p.m. he was delirious and very ill with gross meningeal signs. No definite focal signs could be discovered on neurological examination. Treatment with intramuscular and intrathecal penicillin was begun but the lumbar C.S.F. was now so thick and the flow so sluggish that intraventricular injections were indicated. Accordingly bifrontal burrholes were made and the left lateral ventricle tapped. Here the pressure

was found to be 500 mm. of water and about 30 c.c. of purulent fluid were withdrawn. The right ventricle was only found with difficulty and appeared collapsed. In the light of later experiences this finding should have been interpreted as indicative of an abscess but this was the first of our cases of simultaneous abscess and meningitis, nor were we aware at that time of the prevalence of abscess in streptococcal infections. An intra-ventricular injection of penicillin was therefore given and nothing further was done. The patient died quite suddenly about six hours after operation, and autopsy revealed, in addition to the leptomeningitis, a large subdural collection of pus overlying the right temporal lobe and in relation to the dura over the tegmen tympani.

In order to detect this difficult group of cases the procedure should be as follows:

As soon as meningitis is suspected in a patient who has well-marked signs of otitis or sinusitis he or his relatives should be questioned as to previous attacks and the patient then carefully examined for focal signs. A lumbar puncture is then cautiously performed, the initial pressure of the C.S.F. is measured and 4 to 5 c.c. slowly withdrawn. Cultures are set up and a Gram-stained film immediately examined. If pneumococci are recognized, and the C.S.F. is running freely, a lumbar injection of penicillin is given and the patient treated on the lines already described. If, however, streptococci are seen, an intracranial abscess should at once be suspected, and suspicion is greatly strengthened if the C.S.F. pressure is far in excess of 300 mm. of water or if focal signs have been elicited.¹ A lumbar injection of penicillin may be given at the time of the diagnostic tap, but the presence of an abscess must then be confirmed or excluded by ventricular estimation or ventriculography, since penicillin makes ventriculography safe even in the presence of an active infection.

If no abscess is found the meningitis is treated in exactly the same way as pneumococcal meningitis. The sensitivity of the organism to penicillin should be assessed as some strains of streptococci are relatively resistant. Nevertheless we have not yet needed to exceed our usual range of dosage.

If an abscess is found it must be dealt with surgically in order to prevent a fatal rise in intracranial pressure.

Cerebral abscess.—If the rise in pressure is due to the actual accumulation of pus, rather than to oedema, the abscess should be aspirated and penicillin is then instilled into the abscess cavity. Thorotrast may be injected at the same time, as it does not inactivate penicillin and facilitates subsequent management (Pennybacker, 1945). A more concentrated solution of penicillin is indicated for instillation into an abscess cavity than is advisable for intrathecal injections, and we use a solution of 10,000 u/c.c. as opposed to our standard intrathecal solution of 2,000 u/c.c. The exact amount will to some extent depend on the size of the abscess cavity, but is usually 1 to 3 c.c. If there is abundant pus, aspiration will be enough to control the rise in pressure, but if only a small quantity can be aspirated, the intracranial pressure must be controlled by ventricular taps or drainage. If this too fails the patient will require a decompression over the abscess, as unless the rise in pressure is relieved he will die; but in the presence of meningitis wide opening of the dura should be avoided if possible since the raised intracranial pressure will produce great herniation with corresponding increase in destruction of the brain (Falconer and Russell, 1944; Holbourn, 1944).

Subdural abscess.—A subdural collection of pus is dealt with by the insertion of fine rubber catheters through suitably placed burrholes. Through these catheters, which are left open, pus is aspirated and penicillin instilled. The subdural space does not retain penicillin like the subarachnoid, and four- to six-hourly injections are therefore needed. The number of burrholes required varies, but in one of our successful cases no fewer than five had to be made in order to ensure access to the whole of the subdural collection. When the limits of the subdural abscess have been defined, two further burrholes should be made through which the intraventricular penicillin can be given without passing the brain needle through the infected area.

The concomitant lepto-meningitis is controlled by intraventricular injections of penicillin. These are begun when the diagnostic ventricular tap is performed and continued either by intermittent taps or, if the ventricle is being drained, by instillation through the catheter. The same scale and frequency of dosage is used as with lumbar injections, but unless the intracranial pressure has been adequately lowered by aspiration of the abscess or other means no attempt must be made to treat the meningitis by the lumbar or cisternal route. These are not only useless but highly dangerous. The pressure of the abscess distorts the subarachnoid channels at the tentorial opening and elsewhere, and may prevent the penicillin from reaching the ventricles or spreading upwards over the hemisphere (Cairns, Duthie, Lewin and Smith, 1944). Moreover a lumbar or cisternal puncture carries a very real risk of producing a fatal pressure cone, nor is this risk lessened by an injection of penicillin.

¹Focal signs do not always indicate an abscess, but may be caused by cerebral thrombophlebitis. Thus in one of the cases in this series the patient developed a left hemiplegia and left homonymous hemianopia. Abscess was excluded by ventriculography. The whole of the intrathecal penicillin was given by lumbar injection, and recovery was complete.

history of earache, the tympanic membrane was very thick and scarred with a small anterior attic perforation and offensive purulent discharge; in the third there was a definite history of previous attacks of otitis; and in the fourth the abscess developed in a pre-existing brain fungus. It is thus possible that the abscess really predates the meningitis, although clinically they appear to develop simultaneously. The clinical detection of a complicating abscess may be extremely difficult especially as in none of our cases was any definite papilloedema detected.

In our experience the most important clue in diagnosis is the bacteriology of the infection. In our 26 cases of pneumococcal meningitis secondary to ear and nose infections, only 2 were complicated by an abscess. By contrast, among 9 cases of streptococcal meningitis an abscess was present in 5. An abscess was also found in our one case of otogenic staphylococcal meningitis. This same correlation between the bacteriology and abscess formation is seen in our cases of meningitis from other sources (fig. 2).

FIG. 2.—The incidence of a complicating intracranial abscess in the different bacteriological varieties of meningitis both in the cases forming the present series and in those of meningitis from other sources.

The type of streptococcus was not determined in every case, but there is some indication that abscess is commonest in the anaerobic streptococcal infections (Cairns and Schiller, to be published). The abscess may be intracerebral or subdural or both, but wherever it is its detection is imperative since not only does the abscess itself demand prompt surgical treatment but the meningitis must be treated by intraventricular penicillin instead of by the routine lumbar injections. Owing largely to the difficulties in diagnosis we have not yet succeeded in saving any of our otogenic cases of simultaneous meningitis and abscess. We have, however, been successful in two cases secondary to sinusitis.

CASE VI.—R.I. Illustrating the diagnostic problem of simultaneous meningitis and abscess.

A storekeeper of 47 was admitted to hospital as an emergency under the care of Mr. Livingstone. For the past fifteen years he had suffered from intermittent attacks of mild right-sided earache associated with a thin, watery discharge. Ten days before admission, the pain and otorrhoea returned, but later the discharge ceased and the pain became much worse. Twenty-four hours before admission he had a rigor and his temperature rose steeply.

On admission he was in considerable pain from his ear, his neck was a little stiff, and his temperature just over 100°F. The right external auditory meatus was filled with thick pus. Lumbar puncture revealed a cloudy fluid under a pressure of 240 mm. of water. No organisms were seen on the films and cultures were sterile. Treatment with sulphadiazine was begun, and a few hours later a right radical mastoidectomy was performed, and an extradural abscess opened. The middle fossa was widely exposed until healthy dura was found. The wound was closed with drainage.

Following operation he steadily improved and nine days later began getting up. In the early hours of the tenth day the symptoms of meningitis returned with increased severity. The C.S.F. was found to be frankly purulent and to contain a number of streptococci. By 2.30 p.m. he was delirious and very ill with gross meningeal signs. No definite focal signs could be discovered on neurological examination. Treatment with intramuscular and intrathecal penicillin was begun but the lumbar C.S.F. was now so thick and the flow so sluggish that intraventricular injections were indicated. Accordingly bifrontal burrholes were made and the left lateral ventricle tapped. Here the pressure

By 5.30 p.m. he was desperately ill: there was pronounced head retraction, he was cyanosed, and his respirations which had risen to 40 per minute were interrupted by bursts of hyperpnoea when the rate would rise to 60 or even 70. He was mute and restless and any interference provoked paroxysms of violent but silent struggling. There was a right facial weakness of lower motor neurone type, but no other focal signs. Lumbar puncture yielded turbid fluid under a pressure of over 300 mm. of water and an examination of a smear of C.S.F. showed Gram-positive diplococci. *Pneumococcus* Type 14 was grown on culture.

At 7 p.m., when he came under our care, he seemed in extremis. At this stage treatment was begun with intrathecal and intramuscular injections of penicillin. At 8 p.m. he was seen by Mr. Livingstone who advised against further operation on the ear.

During the next twenty-four hours there was little change in his general condition except that the rapid deterioration ceased. X-rays taken of his mastoids showed evidence of an acute mastoiditis on the right side. Twenty-four hours after treatment with penicillin was begun his temperature fell, and thereafter his recovery was rapid and complete. During his illness he was again seen several times by Mr. Livingstone who was fully satisfied with the progress of the ear. When discharged from hospital, all the clinical and radiological evidence of infection had disappeared. When last seen, two years after the meningitis, there had been no recurrence of symptoms in the right ear, though a few weeks before this he had a mild attack of left-sided otitis media.

Thirteen patients had no operation. As soon as supplies of penicillin were adequate, all received from 120,000 to 320,000 u. daily by intramuscular injection, in addition to their intrathecal penicillin and oral sulphadiazine. This was continued until the active infection had subsided. Although there were four fatalities, in no case would the outcome have been altered by operation on the ear. One infant died a few hours after treatment was begun; here delay in instituting chemotherapy was the decisive factor. Two died from intracranial abscess and one from acute cerebral oedema. In the other 9 cases not only was recovery from the meningitis complete but there has been no return of the aural symptoms. Mr. Macbeth and Mr. Livingstone have seen most of these patients and, except in one (Case II), they have not advised operation. Only 2 of these 9 cases relapsed, and in both the intrathecal course of penicillin had been incomplete. The following case is an example of control of the primary focus without operation.

CASE VIII.—R.I. 20891/44.

The patient, a schoolboy of 11, had always been a backward child. Three years earlier he had begun to suffer from recurrent attacks of right-sided otitis. From time to time he would complain of earache, then after a few days the ear would begin to discharge and the pain would cease. On May 14, 1944, he developed a cold in the head and a purulent discharge from the right ear. Fourteen days later he complained of headache, grew drowsy and restless, and his parents noticed that his head was retracted. These symptoms all steadily increased and after five days he was admitted to hospital elsewhere. A lumbar puncture was performed and hæmolytic streptococci grown from the C.S.F. Treatment with sulphathiazole was begun and the following day he was transferred to Oxford.

Examination at that time showed an ill, wasted child with spina bifida, but no cauda equina symptoms. He was semiconscious and at times would scream with pain from the intensity of his headache. Head retraction and opisthotonus were so marked that he had considerable difficulty in swallowing. Upward movement of the eyes was limited but no other focal signs were found on neurological examination. There was no mastoid tenderness but thick offensive pus, from which a *Staphylococcus aureus* was cultured, was welling through a perforation in the right tympanic membrane. X-rays of the mastoids taken three days later showed sclerotic bone with a few small cells and an opaque antrum.

Treatment with sulphadiazine and intramuscular penicillin was begun immediately. In view of the possibility of a complicating brain abscess, the lateral ventricles were tapped through frontal burrholes. Both were found to be dilated which made the presence of an abscess unlikely. On culture, *Staphylococcus aureus* was grown from the ventricular and *B. hæmolytic streptococcus* from the lumbar fluids. Intrathecal penicillin was given by ventricular and lumbar injections and he made a slow but satisfactory recovery from his meningitis.

Mr. Macbeth saw this patient in acute phase of the illness and in view of our past experiences he thought it justifiable to await developments before advising operation. This course was fully justified by subsequent events. Six days later the perforation had healed and by the time the meningitis was fully controlled Mr. Macbeth declared himself satisfied with the ear. Follow-up studies during the subsequent eighteen months showed recovery both from the meningitis and the otitis to be complete.

Two patients were operated on during convalescence. The first was the patient on whom complete mastoidectomy was performed some weeks after a relapse of the meningitis (Case II). The second was a girl of 14 who developed an acute right-sided mastoiditis two months after she had apparently made a complete recovery from an attack of pneumococcal meningitis secondary to a mild right otitis media. Mastoidectomy was performed elsewhere, and a pure culture of *Staphylococcus aureus* grown from the pus. Though the relation between the original otitis media and the mastoiditis is therefore uncertain, operation early in convalescence would have prevented the second attack.

Our successful cases in which no mastoidectomy was performed include examples of chronic otitis as well as of recurrent (Cases VII and VIII) and acute otitis. In every case the

In those cases of streptococcal meningitis where the patient's general condition is good, when there are no focal signs, or clinical evidence of an excessive rise in intracranial pressure, and where the C.S.F. pressure is under 300 mm. of water, it is probably justifiable to institute treatment by the lumbar route, provided the patient is closely watched for signs of rising intracranial pressure and provided also that full facilities exist for immediate ventricular puncture should the need arise. Even so an abscess may be missed. We have had 2 patients who fulfilled the above criteria and yet were later shown to have a small abscess. The danger signals are a progressive rise or fall in the pulse-rate, periodic respiration, and an increase in stupor. The need for constant observation cannot be exaggerated, and while the possibility of abscess exists these cases really demand the whole of the surgeon's time and attention.

Our experience with staphylococcal meningitis is very limited, but the fact that 2 out of our 3 cases have been complicated by abscess suggests that staphylococcal and streptococcal meningitis present similar problems.

(3) Treatment of the Primary Focus of Infection

Since the time of Gowers (1888) immediate surgical drainage of the primary focus of infection has generally been considered axiomatic in the treatment of otogenic meningitis. Valuable as sulphonamides are in the treatment of meningitis, opinion is still divided as to whether or not they have lessened the need for immediate operation on the primary focus. Thus Watkyn-Thomas (1941) defined the principles of treatment as: (1) Elimination of the primary focus; (2) drainage of the subarachnoid space; (3) appropriate counter-medication.

Now that penicillin is available the place of operation in treatment should be reassessed by otologists, and in this connexion our experiences in conjunction with our otological colleagues may be of interest. Our series of 21 cases of otogenic meningitis has been analysed according to the incidence and time of operation, the history, the recovery rate and cause of death (Table II).

TABLE II.—TWENTY-ONE CASES OF OTOGENIC MENINGITIS SHOWING THE TIME-RELATION OF OPERATION ON THE EAR TO THE COURSE OF THE ILLNESS, THE PREVIOUS HISTORY, THE RESULT AND THE CAUSE OF DEATH.

Operation	No. of cases	Previous otitis	Recovered	Died	Cause of death
Mastoidectomy before meningitis ...	3	2	2	1	Abscess
Mastoidectomy at height of meningitis ...	3	1 (?)	2	1	Heart failure and inhalation pneumonia
Myringotomy at height of meningitis ...	1	1	1	0	—
Mastoidectomy during convalescence ...	2	1	2	0	—
No operation...	13	4	9	4	(i) Delay in chemotherapy, (ii and iii) abscess, (iv) acute cerebral oedema

One patient (Case II) had two operations. Previous otitis = a previous history of infection of the ear.

In 3 cases mastoidectomy failed to prevent the development of meningitis several days later, though in one the operation was admittedly incomplete. It is possible that a prophylactic course of systemic penicillin, given either alone or with sulphonamides, over the period of operation might prevent the development of meningitis in such cases, since a protective action has been claimed for sulphonamides alone (Weinstein, 1942).

Three patients had been operated upon at the height of the meningitis before they came under our care. In the 2 who recovered mastoidectomy preceded the institution of penicillin therapy by three days and three weeks respectively. In neither had it had any apparent effect on the meningitis which was already partially controlled by sulphonamides. In the fatal case mastoidectomy was performed immediately before penicillin therapy was begun. The patient had a stormy time during operation; he stopped breathing, and was with difficulty resuscitated. The following day he developed heart failure and died. A severe inhalation pneumonia was found at autopsy.

The single case in which an emergency myringotomy was done was one of fulminating pneumococcal meningitis.

CASE VII.—R.I. 23632/44 (Falconer *et al.*, 1946. Case III).

The patient, a schoolboy of 15, had an attack of right-sided otitis media in December 1943. This responded well to sulphonamides and he returned to school the following term. At 4 p.m. on April 14, 1944, he had a recurrence of his earache and his temperature rose to 102.5°F. The ear was examined, and though the tympanic membrane was reddened no indication for operation was found. He was given 2 grammes of sulphadiazine and thereafter received 1 gramme every four hours. Next morning at 4 a.m. he awoke complaining of headache and vomited, by 11.30 a.m. he was delirious and had considerable neck rigidity; the tympanic membrane was bulging. He was transferred to a nursing home where at 2.30 p.m. a myringotomy was performed and a fair quantity of pus released without any effect on his general condition. Since he was by now unable to swallow the sulphadiazine was continued by intramuscular injection.

difference in the prognosis is apparent when the causes of death are considered (fig. 5). A complicating abscess is the commonest cause of death, and the combination of abscess and meningitis is most common in streptococcal infections. In our 6 fatal cases of pneumococcal meningitis, in 2 only was death due to abscess formation. Three patients died from delay in instituting chemotherapy, and 1, a traumatic case, from fat embolism while recovering from his meningitis. Although we have not yet been fortunate enough to cure a patient in whom meningitis and abscess followed disease of the ear, our successes with cases secondary to sinusitis encourage us in the belief that no patient is too ill to recover with chemotherapy and suitable surgical intervention.

SUMMARY

Otogenic meningitis and meningitis secondary to infection of the nasal sinuses are considered together, since the problems of treatment are similar. Such cases fall into three main groups: (1) Those in which no organisms are recovered from the C.S.F.; (2) those due to organisms which are relatively or totally resistant to penicillin; (3) those due to penicillin-sensitive organisms.

A series of 37 cases (Table I), of which all but one fall into the third group, is described. The predominating organisms were pneumococci and streptococci.

The basic treatment of purulent meningitis with penicillin is briefly recapitulated, the mechanism of relapse discussed, and the hazards associated with the administration of penicillin intrathecally are pointed out.

Eight cases have been encountered in which the meningitis was complicated by an intracranial abscess. Diagnosis of the abscess is difficult, since both abscess and meningitis appeared to develop simultaneously, but its detection and immediate treatment are imperative. This combination of abscess and meningitis is seen most often in streptococcal infections. In our total series, out of 38 cases of pneumococcal meningitis, only 2 were complicated by an abscess, while out of 10 streptococcal cases, a concomitant abscess was present in 6.

The treatment of the primary focus of infection is discussed since the use of systemic penicillin demands reassessment of the place of emergency mastoidectomy in the treatment of otogenic meningitis. In 21 otogenic cases with 15 recoveries only 2 patients had a mastoidectomy at the height of the meningitis; 13 patients had no operation on the ear, and of these 9 recovered completely from both the meningitis and the otitis. In none of the fatal cases could mastoidectomy have saved the patient's life, and, in fact, operation with general anaesthesia may tip the scales against the patient when performed at the height of an attack of meningitis. Whether operation is still necessary once the meningitis has been controlled is a matter which must be decided by the otologist.

In the present series of cases the results with pneumococcal have been better than with streptococcal meningitis owing to the frequency with which the latter disease has been complicated by intracranial abscess.

Finally we would like to thank our colleagues, Mr. Macbeth and Mr. Livingstone, for allowing us to treat their cases, and for the help they have given us with our own cases.

Mr. J. Eric Paterson: My observations are based on material treated in the Neurosurgical Unit at Killearn Hospital, near Glasgow. The Unit was established four years ago, and the material includes therefore cases treated before and after the advent of penicillin. It is selected material; most of the cases have been referred, either from an otologist or from a fever hospital, because progress was unsatisfactory, because some such complication as brain abscess was feared, or because it was felt that penicillin administration by some special route, such as into the ventricle, should be carried out.

In our penicillin cases we have had only 6 patients with uncomplicated otic menin-

case with which the initial attack of meningitis was controlled was approximately the same. Nor did the 6 patients who had had a mastoidectomy done before they came under our care respond better to treatment than those who had not. In fact, in 1 fatal case the stress of anaesthesia and operation at the height of the meningitis probably prejudiced the patient's chance of recovery.

Though we have thus no evidence that operation is of value in treatment of the acute phase of the meningitis, it sometimes has a place in the treatment of the relapsing case. That the meninges can be reinfected from the primary focus is certain (Case II), but what is not known is how frequently this occurs. Evidence is accumulating that reinfection from an intrathecal fibrino-purulent collection (Case III) is the commoner mechanism. During treatment of a case of meningitis, whether otogenic or secondary to sinusitis, in which relapse follows relapse, the idea of an active primary, extrathecal focus which is constantly reinfected the meninges is very difficult to resist. Nevertheless, in our experience, attempts to stop relapse by operative treatment of extradural sources of infection have been disappointing.

Whether early operation is necessary in order to preserve hearing is not a matter for us to decide. It is, however, interesting that while several of our patients have been slightly deaf on first recovering consciousness, in only 2 has this been permanent. In neither case was the meningitis otogenic and in both the deafness was of nerve type.

Our experience with penicillin thus suggests that mastoidectomy need no longer be performed as an emergency in cases of otitic meningitis. In this connexion it is interesting that work done on experimental pneumococcal infections in animals shows that general anaesthesia (alcohol, ether and avertin) inhibits the activity of the leucocytes and allows the organisms several hours in which to multiply unchecked (Pickrell, 1938).

Once the meningitis has been cured, whether mastoidectomy is still required, and whether this depends on the chronicity of the otitis, are questions which must be answered by the otologist. It is likely that the answer may be most easily found from study of cases of otitis uncomplicated by meningitis. It is, however, clear from the observations made by our otological colleagues on cases in this series that, at least in the acute case, full recovery can be attained by systemic chemotherapy. In any case, the patient is dying not from the mastoiditis but from his meningitis. Prompt and adequate treatment of the meningitis must therefore take precedence over other therapeutic measures.

The treatment of acute sinusitis is less debatable. Adequate doses of penicillin can control the infection, even when this is complicated by frank osteitis of the skull. Even if this becomes reactivated after withdrawal of the systemic penicillin it can be dealt with at leisure after the meningitis is controlled.

When meningitis follows a fracture through the sinuses with tearing of the dura, the dural defect should be repaired as soon as the patient has recovered from his meningitis (Cairns, 1937). Similar treatment is not so often required for fracture of the petrous bone with tear of the overlying dura.

RESULTS

In our 37 cases there have been 26 recoveries and 11 deaths (fig. 3). Up to the present time the prognosis has usually been considered best in cases of streptococcal and worst

FIG. 3.—Classification of the results according to the mode of primary infection.

FIG. 4.—Bacteriological classification of results.

FIG. 5.—Table showing the causes of death.

in cases of pneumococcal meningitis (Hutchison, 1942; Weinstein, 1942). Our results are very different. Out of 26 cases of pneumococcal meningitis, 20 recovered, while out of 9 cases of streptococcal meningitis, only 5 recovered (fig. 4). The reason for this

difference in the prognosis is apparent when the causes of death are considered (fig. 5). A complicating abscess is the commonest cause of death, and the combination of abscess and meningitis is most common in streptococcal infections. In our 6 fatal cases of pneumococcal meningitis, in 2 only was death due to abscess formation. Three patients died from delay in instituting chemotherapy, and 1, a traumatic case, from fat embolism while recovering from his meningitis. Although we have not yet been fortunate enough to cure a patient in whom meningitis and abscess followed disease of the ear, our successes with cases secondary to sinusitis encourage us in the belief that no patient is too ill to recover with chemotherapy and suitable surgical intervention.

SUMMARY

Otogenic meningitis and meningitis secondary to infection of the nasal sinuses are considered together, since the problems of treatment are similar. Such cases fall into three main groups: (1) Those in which no organisms are recovered from the C.S.F.; (2) those due to organisms which are relatively or totally resistant to penicillin; (3) those due to penicillin-sensitive organisms.

A series of 37 cases (Table I), of which all but one fall into the third group, is described. The predominating organisms were pneumococci and streptococci.

The basic treatment of purulent meningitis with penicillin is briefly recapitulated, the mechanism of relapse discussed, and the hazards associated with the administration of penicillin intrathecally are pointed out.

Eight cases have been encountered in which the meningitis was complicated by an intracranial abscess. Diagnosis of the abscess is difficult, since both abscess and meningitis appeared to develop simultaneously, but its detection and immediate treatment are imperative. This combination of abscess and meningitis is seen most often in streptococcal infections. In our total series, out of 38 cases of pneumococcal meningitis, only 2 were complicated by an abscess, while out of 10 streptococcal cases, a concomitant abscess was present in 6.

The treatment of the primary focus of infection is discussed since the use of systemic penicillin demands reassessment of the place of emergency mastoidectomy in the treatment of otogenic meningitis. In 21 otogenic cases with 15 recoveries only 2 patients had a mastoidectomy at the height of the meningitis; 13 patients had no operation on the ear, and of these 9 recovered completely from both the meningitis and the otitis. In none of the fatal cases could mastoidectomy have saved the patient's life, and, in fact, operation with general anaesthesia may tip the scales against the patient when performed at the height of an attack of meningitis. Whether operation is still necessary once the meningitis has been controlled is a matter which must be decided by the otologist.

In the present series of cases the results with pneumococcal have been better than with streptococcal meningitis owing to the frequency with which the latter disease has been complicated by intracranial abscess.

Finally we would like to thank our colleagues, Mr. Macbeth and Mr. Livingstone, for allowing us to treat their cases, and for the help they have given us with our own cases.

Mr. J. Eric Paterson: My observations are based on material treated in the Neuro-surgical Unit at Killearn Hospital, near Glasgow. The Unit was established four years ago, and the material includes therefore cases treated before and after the advent of penicillin. It is selected material; most of the cases have been referred, either from an otologist or from a fever hospital, because progress was unsatisfactory, because some such complication as brain abscess was feared, or because it was felt that penicillin administration by some special route, such as into the ventricle, should be carried out. In our penicillin cases we have had only 6 patients with uncomplicated otitic menin-

gitis, that is, unassociated with other intracranial lesions such as brain abscess. Two of the 6 cases died, both had been sent in late.

The sulphonamides in acute otitic meningitis.—We give a course of sulphonamide in every case in very large doses. Until recently we used sulphamezathine, since with this drug the risk of renal complications is very small; but since Kremer, Phillips and Stanier (1945) showed that it was most difficult to obtain with it an effective concentration in the cerebrospinal fluid we have used sulphadiazine, with which the concentration has been shown to reach 60 to 80% of the blood level. We have not yet experienced renal crystallization or agranulocytosis. We give a dose of 5 grammes and continue with 3 grammes four-hourly for the first twenty-four hours, followed by 2 grammes four-hourly for a week, when we allow one to two days to elapse without sulphonamide before beginning another such course, if this is thought advisable. When a sulphonamide is used alone—and it must not be forgotten that meningitis may result from a penicillin-resistant organism—the risk of sulphonamide poisoning must be balanced against the risk of a fatal ending in these grave cases. Following the lead of Mr. Norman Dott we have deliberately taken this risk. I know of one patient in whom, over a period of three weeks, a total of 318 grammes was administered, with final recovery; that is, an average dose of $2\frac{1}{2}$ grammes every four hours throughout.

There were some excellent results in pre-penicillin days in streptococcal infections. One case of chronic otitis media which sustained a fracture through the petrous bone had acute meningitis with pus under the temporal fascia. Recovery was rapid after sulphonamide administration and a mastoid operation.

Penicillin therapy.—Our intrathecal doses have hitherto been generally not more than 40,000 units daily, but I shall increase the dosage in the light of what has been said, particularly now that the drug is available in an increasingly pure form. Penicillin reactions have occurred in a few of our cases: several patients complained of pain in the feet, which disappeared when the intrathecal injections were stopped. This we ascribed to an irritation of the cauda equina. Two cases ran a mild temperature, which fell at once to normal when the drug was withdrawn.

Intraventricular penicillin is given when there are signs of a cerebrospinal fluid block, but patients with obstructive hydrocephalus, sent to the neurosurgeon late, do badly; treatment must be prophylactic, early. For instance, a girl of 8 was admitted from a fever hospital. She had papilloedema, bilateral sixth and right seventh nerve palsies. Ventriculograms showed a large hydrocephalus; the fourth ventricle was dilated, but the gas had failed to pass into the cisterna magna or forward along the base. She died sixteen days after admission; intrathecal, intraventricular and systemic penicillin was powerless to deal with the obstruction at the foramina of Luschka and Magendie.

But these foramina are small in size, and there are cases where, in the absence of signs of cerebrospinal fluid block, penicillin given intrathecally may be much less effective than when given by the ventricle. We have only very recently begun to estimate the cerebrospinal fluid bacteriostatic level, but the result is not available immediately, and it would seem wise to begin ventricular administration as soon as the sample of fluid has been taken, without waiting for the result. Here is a case which illustrates the importance of giving intraventricular penicillin in the apparent absence of obstruction. A girl of 7 was admitted a week after an acute head injury. There were a cerebrospinal fluid otorrhoea and a staphylococcal meningitis. Under systemic and intrathecal penicillin she continued to run a temperature for three weeks, with varying, but often high, cerebrospinal fluid cell-count, while her general state deteriorated. Finally, when the count rose to 2,400, ventriculography was done. This disclosed ventricles which were normal in size, without any evidence of obstruction throughout the cerebrospinal fluid pathways. Intraventricular penicillin was started at once and the temperature fell to normal two days later; recovery was uneventful.

Reaction to intraventricular penicillin.—Johnson and Earl Walker (1945) describe the case of a boy of 22 months who was given a dose of 50,000 units by this route. He became unconscious and so collapsed that his blood-pressure could not be estimated. Three hours later he had a generalized convulsion, and this latter was repeated, without loss of consciousness, when he was given another injection three days later. In the case of the little girl just described there was likewise a considerable degree of collapse, without any convulsion; fortunately this is the only example we have had in our series. It is to be anticipated that such disturbances will become less frequent as the drug becomes available in purer form.

Cisternal penicillin.—Little need be said about administration into the cisterna magna. Its place must be very limited indeed. Speaking as a neurosurgeon, I know I should

much rather inject the drug into a ventricle than try to tap a cisterna magna in a child with pronounced opisthotonos. However, I have notes of one case of pneumococcal infection in which a spinal block developed, and which made an excellent recovery with intracisternal penicillin.

Systemic penicillin.—Systemic administration is a most important part of the treatment of these cases; the difficulty is to know how long to continue the drug by this route; usually we play for safety and continue possibly longer than we need to. But we must not exaggerate the efficacy of systemic penicillin in acute meningitis or agree with Reese (1944) when he states that intrathecal penicillin is never necessary, since the drug is excreted into the cerebrospinal fluid in bacteriostatic concentration when the choroid plexuses are rendered more permeable by the disease. As the work of Professor Cairns and his associates has shown, in pneumococcal meningitis only traces of penicillin appear in the cerebrospinal fluid after the systemic injection of even very large doses.

I agree with Professor Cairns that operation on the infected ear should not be carried out in the acute phase of the meningeal infection before this is under control. In systemic penicillin we have a most potent weapon in the control of the spread of the infection from the primary focus to the meninges, and we must exploit it to the full. Operation under general anaesthesia may well turn the scale against recovery; and operation under local anaesthesia must be extremely difficult in a restless, delirious patient. But reinfection of the meninges may readily occur, and if operation is indicated it should be carried out as soon as acute infection has been overcome, while the patient is still on his initial course of systemic penicillin.

Rigid asepsis in intrathecal and intraventricular administration is of extreme importance.—In the past three years I have treated three cases of staphylococcal meningitis following lumbar puncture. Two of these followed spinal anaesthesia, and there were two deaths in this small series.

Mr. R. G. Macbeth said that Dr. Honor Smith and Professor Cairns had asked him to comment on the otological aspect of their communication. It was obvious that with the coming of penicillin therapy otologists must accept a greatly changed outlook on the question of when or even whether they should open mastoids in the presence of otogenic meningitis. One thing which did emerge was that the mastoid operation need no longer be a matter of great urgency. One could safely delay doing a mastoid operation until the meningitis was under control, and the patient therefore more fit for operation.

In acute cases it seemed necessary only to do the simplest operation productive of drainage of the middle-ear cleft. Where the ear was discharging already, no operation might be needed; where there was no discharge, a myringotomy might suffice. Penicillin did not sterilize pus inside an abscess cavity, but it would aid the resolution of an inflammatory process within a draining middle-ear cleft. A patient who had an extradural abscess in the middle or posterior fossa was an exception to that rule, and it was probable that one could get a hint about such a case from careful attention to clinical signs. For example, such a patient might complain of persistent pain and tenderness behind the ear in spite of adequate chemotherapy, and continue to have otorrhœa and cells in the cerebrospinal fluid.

Relapsing cases of meningitis seemed to be commoner with nasal-sinus infections than with mastoiditis, as one would expect from a consideration of the connexions between the nasal sinuses and the subarachnoid space.

It seemed likely that operation would be called for in almost every case of meningitis due to chronic otitis. It was difficult to imagine that a sufficiently high concentration of penicillin could be delivered to deal with the primary focus in chronic bony disease.

Mr. T. B. Layton said that no distinction had been made in the paper presented by Dr. Honor Smith between chronic ear disease and acute inflammations of the middle-ear cleft. In every paper dealing with an otological subject that distinction must be made. The two diseases were as distinct clinically, bacteriologically, and therefore pathologically, and in their response to treatment, as were acute peritonitis and tuberculous peritonitis.

He disagreed with Mr. Paterson that it might become unnecessary to operate on the acute ear, but that operation had still to be done on the chronic ear. He had made the planned experiment of refraining from operating in meningitis of an acute ear because he thought that a condition of the heart was the dominating lesion which would forbid a general anæsthetic to be given. The patient came out of the meningitis but relapsed. He then had operated, but the patient died. He would find it a very grave responsibility to refrain from removing that factory of organisms which was down against the dura mater. There was a distinct difference in disease of the ear and the sinuses. One was a disease of bone, contiguous with which was the periosteum—the dura mater, and therefore the spread from one to the other was easy and rapid; the other was an inflammation of a mucous membrane separated from the cranial cavity by two layers of periosteum and an intervening piece of bone, and all one could do was to drain that cavity, if one knew exactly from which of the half dozen or so channels it was spreading through to the meninges.

Mr. E. Musgrave Woodman said that those working so extensively on penicillin were to be congratulated on the change that had taken place in the prognosis of pneumococcal meningitis. He had always been taught that pneumococcal meningitis was an incurable disease.

Why was it that penicillin seemed so impotent to control a migrating streptococcal abscess in the brain?

As to whether they should operate on an acute mastoid which was accompanied by meningitis or brain abscess, they had all been taught that the primary focus should be removed when consequential complications arose. But these patients were very ill, their margin of safety was low, and a little thing would tip them over the border. In the best interests of the patient it might be that a simple drainage without eradication should be carried out.

Mr. C. P. Wilson said that probably those cases which developed symptoms associated with a cerebral abscess were more likely to go to a neurosurgical unit than to an otologist. In his 8 cases of otitic meningitis there had been only one death. That was in a pneumococcal case. 3 cases had grown a hæmolytic streptococcus which had been recovered.

Intrathecal dosage.—He had discussed this with Professor McIntosh, pathologist, Middlesex Hospital. Originally these cases were given 2,000 units per c.c. intrathecally according to the amount of cerebrospinal fluid removed, but lately they had been as much as 50,000 units in otitic and non-otitic cases. He queried this amount, Professor McIntosh, because he felt it was much more likely to produce a reaction with fibrinous exudate, but Professor McIntosh's opinion was that often had fibrinous exudate without penicillin, and he (Professor McIntosh) had often had the amount of exudate was not greater with penicillin, but it was not serious. In this series they had had only two complications: paralysis of the median nerve which was now recovering, and a case of *petit mal*. Thus the disadvantage of using very large doses intrathecally did not seem to have been particularly borne out in Professor McIntosh's experience at Stoke.

Mr. L. Graham Brown said that four months ago he had a case of a flare-up on a chronic infection. He carried out a complete mastoidectomy. The patient did very well for three weeks and then developed a facial palsy. The wound and cleaned up the infection still present. Since the palsy continued he carried out a cerebrospinal examination and found abscess. He called in a neurologist, who, however, could not locate anything. The patient was put upon sulphonamide treatment and penicillin systemically. Very well, the wound healed up completely, the temperature fell, and the patient returned to the hospital. A month later, however, he returned with further palsy. He (Mr. Graham Brown) suspected suffering from a sphenoidal abscess, but his hand was stayed by the fact that the patient was ready to operate, but before any further information could be obtained he died. At post-mortem a temporosphenoidal abscess was found.

This case was interesting from the point of view of the relation between the otologist and the neurosurgeon and neurologist. It was obvious

a little difficulty in carrying out completely all those difficult tests and treatments which the neurosurgeon was now making his own. He desired to ask Professor Cairns if he did not agree that, in those cases where brain abscess or an intracranial complication was suspected accompanying meningitis, the neurosurgeon should take charge. He was one of those otologists who thought that these cases were really getting beyond their range of full responsibility.

Mr. Terence Cawthorne said that a contribution from outside was always welcome at that Section particularly when it carried with it the experience of the Neurosurgical Department at Oxford. Penicillin had quite clearly altered in some respects their views of otogenic meningitis. He desired to ask whether there was any likelihood of systemic penicillin being able to be a substitute for intrathecal medication. These constant lumbar punctures were a source of trouble and possibly a danger. He had seen two cases of meningitis secondary to lumbar puncture, both in cases in which spinal anaesthesia was carried out, and the organism in each case was *B. pyocyaneus*.

Mr. Layton's very forcible exposition of the importance of differentiating between acute and chronic otitis media would command general agreement. They were two quite different diseases when it came to the management of an otogenic meningitis. On the question of draining a primary focus it might be asked, what was a primary focus? Meningitis following rapidly upon an otitis media was a mucous membrane disease not a bone disease, and the infecting focus could not be eradicated by carrying out wide surgical excision of bone. This only made it easier for infection to spread even further. The meningitis which followed within hours or days upon an otitis media should be dealt with conservatively.

Meningitis following upon a long-standing otitis media was a different matter. He had in the past said that he thought such cases should be operated on without delay, but he now felt that it was wiser to give chemotherapy and the antibiotics a day or two's start before operation. He had no doubt that in cases of intracranial complications of chronic suppurative otitis media the best way of getting a good result was by intimate co-operation between the otologist, the neurologist and the neurosurgeon.

Mr. F. W. Watkyn-Thomas said that to control meningitis by any chemotherapeutic method, sulphonamide or penicillin, they must have an agent which would penetrate the perivascular sheath, pass along the vessels, and percolate the brain substance. The sulphonamides passed the choroid plexus, entered the ventricles and passed, by the perivascular spaces, through the brain. Was there evidence that penicillin, unless administered by the intraventricular route, would do that? To what extent would intrathecal penicillin do anything except pass over the outer surfaces and eventually be absorbed? Would it actually enter the brain substance? He knew that theoretically it was possible to get a reverse current of the cerebrospinal fluid, but was there any evidence that that occurred in penicillin administration? He was deeply impressed, but not quite convinced by Dr. Honor Smith's paper, and he did not think that he was going to abandon the removal of the focus when there was one. Later on he might be converted.

Mr. H. V. Forster said that only a few days ago he had been asked to examine a man who had recovered from acute purulent meningitis associated with a history of inflammation in one ear. Intrathecal and systemic penicillin had been successfully given.

At his, Mr. Forster's, examination, the middle-ear disturbance was found to have subsided and the drumhead to be intact.

In earlier days before sulpha and penicillin therapy, one expected to see few cases recover from meningitis, complicating an acute primary otitis media.

In acute inflammation of the middle-ear cleft, he had always felt that early drainage through its bony walls should be withheld and would like to support Mr. Cawthorne's views on the pathology of this type of infection.

In chronic otitis media with an exacerbation, complicated by meningitis of markedly purulent type, it had not been unusual in earlier days to see recovery after eradication of the primary focus of disease, assisted by lumbar puncture. Perhaps a certain degree of immunity had been developed through the years of chronic infection. In such cases, the possibility of a complicating brain abscess would confront the otologist who need not fear to explore for it with the serum needle and a syringe to provide suction to draw off the pus. He had great confidence that if the abscess cavity were entered by the needle, pus would not refuse to be drawn into the barrel of the syringe. He did not think that to explore through the roof of the operation cavity in this way gave any serious

risk of infecting healthy brain tissue and the resulting instrumental trauma was not greater than that following the puncture in ventriculography.

Fatal cases of otitic brain abscess followed to the post-mortem room rarely showed an undrained loculus but a condition of spreading encephalitis.

Was there any evidence to show that penicillin was able to control the advance of the encephalitis?

The President said that this interesting discussion could be summed up by saying that certainly penicillin did hold out the hope of helping cases which were hopeless in the past. It had also demonstrated the need for co-operation between the otologist and the neurosurgical units, and they were very grateful to Oxford for setting such an outstanding example of this.

Professor Hugh Cairns, who replied on the Discussion, said this subject had reached a stage at which the pathology of the primary focus had become of urgent clinical interest. The use of modern antibiotics in any field of pathology raised individual problems peculiar to that field, and the question of the infection of the mastoid and petrous bone was no exception to this rule. Neurosurgeons and other people working at Oxford had been drawn closer to the otologist over the use of penicillin than they had ever been before. He thought particularly of the cases of pneumococcal meningitis where relapse occurred. The patient got cured of one attack of pneumococcal meningitis and then got another, and this sequence might go on for months, and they found themselves badgering their otological colleagues to come and tell them whether there was a primary focus in the ear which was still active and whether it ought to be operated on, rather hoping that they would say "Yes." That was just one example of the type of thing with which they were now confronted.

The dosage of intrathecal penicillin.—They were very much against large doses; the standard dosage intrathecally should be about ten thousand units in one dose. It might be given twice a day in the very acute phase of the meningitis, but for most of the time it was sufficient to give it once a day. Excessive doses could cause trouble—fits, retention of urine, and other symptoms of damage to the cauda equina. Furthermore, all the available evidence went to show that excessive dosage was unnecessary. With the dosage recommended a concentration of penicillin in the cerebrospinal fluid would be obtained which was more than ample to destroy any of the ordinary pathogenic bacteria like pneumococci or streptococci.

Intrathecal treatment must be systematic, and the least time for intrathecal treatment in a proved case of pathogenic meningitis was five days. Often it was desirable to go on for rather longer.

What penicillin could do prophylactically, both for infection at the mastoid and infection at the brain, had yet to be proved. Mr. Watkyn-Thomas put a fundamental point when he asked whether the penicillin could diffuse into the brain from the capillaries. The answer was that nobody knew, and it was an extremely difficult problem to work at experimentally. It was known that, given systemically, the penicillin would not pass in any appreciable amount into the theca. It was also known that patients who were given penicillin systemically in adequate doses would still have relapses of meningitis. Therefore, in answer to Mr. Cawthorne's question, he did not think there was any likelihood, with the present compounds, that systemic treatment would replace intrathecal treatment.

If Mr. Layton would read the opening paper he would find that they had in fact distinguished between the acute and the chronic cases. A chronic focus, where there was a collection of pus or sequestra, ought to be dealt with surgically. However, he was not clear from what had been said whether Mr. Layton would hold his hand in any case or whether he would go ahead and operate on all of them, acute and chronic, as he did in the old days. As far as osteomyelitis of the long bones was concerned surgeons had changed their views very considerably since the advent of penicillin.

Patients who got an attack of pneumococcal meningitis did not seem to become more immune, at any rate not for a long time. Relapses, of which there might be eight or nine in one case, were just as severe as the initial attack. If each attack of meningitis were treated as patiently and energetically as the first, and the surgeon in charge did not lose heart or allow the nurses to lose heart, success would be achieved and the patient would in the end cease to relapse.

There was a great field here for the otologist to work out precisely the degree to which penicillin could help him in the treatment of mastoid infection and also in its prevention in cases of otitis media.

Phthisis in the Seventeenth Century

Growth and Development of Knowledge¹

By Professor S. LYLE CUMMINS, C.B., C.M.G.

THE early part of the seventeenth century marks the beginning of a great expansion of experiment and fact in medicine in general and in the treatment of tuberculosis in particular. The domination of thought by the ancient observations of Hippocrates (460 B.C.) and of Galen (A.D. 131-200) was giving way before the results of research and growing points of positive knowledge were apparent on all sides. Noteworthy among these was the discovery of the "lesser" or "pulmonary" circulation of Realdus Columbus (1510-1599) of Cremona. "The blood", he says, "goes through the vena arteriosa to the lungs; then, mixed with the air, it goes through the arteria venosa to the left heart" (Guthrie, *Hist. Med.*, 1945). But the mightiest step forward in medical research was the discovery of the complete circulation of the blood through the whole body, activated by the motion of the heart, demonstrated by William Harvey (1574-1657) in 1616 and, after complete verification, published by him in his great work, *De Motu Cordis* in 1628. The first English work on phthisis to which I have so far had access is the *Theatri Tabidorum Vestibulum* of Christopher Bennet (1617-1655). This author was born when Harvey was 39 years old and at the prime and fruition of his work; a year after he had made his great discovery and eleven years before he gave it, in its published form, to the world. It is a feature in medical research that great discoveries, duly published, have a galvanizing effect on medical thought. Christopher Bennet, as a graduate of Oxford, must have been aware of Harvey's work though not, perhaps, as appreciative of its importance as we are to-day. His theory of the development of a phthisis or consumption of the lungs may or may not be founded on it. "From this Incitement of the Blood", he says, "which, for the most part, is the Efficient of Secretion, and from the Expression of Serum from the lungs, moderately be-dewing them, a frequent spitting will sometimes be raised; but if a Person is overflowed with a great Profusion of such Serosities which induce a general Laxity, a more protracted Ptyalism will succeed: From the collection of more dense Fluids the Bronchi will be stuffed; from a thinner matter insinuating inwardly they will be distended or their Lobes, being in some wise infected, will rise upwards; and lastly, from a settled and most gross (not to say malignant) Instuffation will arise a very dangerous Asthma." . . . "Yet, in my opinion, the Universal Taint of such Exhalations will sooner bring on that Debility in the course of an Obstinate Phthisis than if the Blood had failed in its Consistence." I leave it to the readers whether, in truth, this passage has any flavour of Harvey or not! Poor Bennet had at least the right to think out, as far as he was able, the mechanism of phthisis for he himself suffered from the disease.

¹See *Proceedings* (1914) July, 37, 517.

risk of infecting healthy brain tissue and the resulting instrumental trauma was not greater than that following the puncture in ventriculography.

Fatal cases of otitic brain abscess followed to the post-mortem room rarely showed an undrained loculus but a condition of spreading encephalitis.

Was there any evidence to show that penicillin was able to control the advance of the encephalitis?

The President said that this interesting discussion could be summed up by saying that certainly penicillin did hold out the hope of helping cases which were hopeless in the past. It had also demonstrated the need for co-operation between the otologist and the neurosurgical units, and they were very grateful to Oxford for setting such an outstanding example of this.

Professor Hugh Cairns, who replied on the Discussion, said this subject had reached a stage at which the pathology of the primary focus had become of urgent clinical interest. The use of modern antibiotics in any field of pathology raised individual problems peculiar to that field, and the question of the infection of the mastoid and petrous bone was no exception to this rule. Neurosurgeons and other people working at Oxford had been drawn closer to the otologist over the use of penicillin than they had ever been before. He thought particularly of the cases of pneumococcal meningitis where relapse occurred. The patient got cured of one attack of pneumococcal meningitis and then got another, and this sequence might go on for months, and they found themselves badgering their otological colleagues to come and tell them whether there was a primary focus in the ear which was still active and whether it ought to be operated on, rather hoping that they would say "Yes." That was just one example of the type of thing with which they were now confronted.

The dosage of intrathecal penicillin.—They were very much against large doses; the standard dosage intrathecally should be about ten thousand units in one dose. It might be given twice a day in the very acute phase of the meningitis, but for most of the time it was sufficient to give it once a day. Excessive doses could cause trouble—fits, retention of urine, and other symptoms of damage to the cauda equina. Furthermore, all the available evidence went to show that excessive dosage was unnecessary. With the dosage recommended a concentration of penicillin in the cerebrospinal fluid would be obtained which was more than ample to destroy any of the ordinary pathogenic bacteria like pneumococci or streptococci.

Intrathecal treatment must be systematic, and the least time for intrathecal treatment in a proved case of pathogenic meningitis was five days. Often it was desirable to go on for rather longer.

What penicillin could do prophylactically, both for infection at the mastoid and infection at the brain, had yet to be proved. Mr. Watkyn-Thomas put a fundamental point when he asked whether the penicillin could diffuse into the brain from the capillaries. The answer was that nobody knew, and it was an extremely difficult problem to work at experimentally. It was known that, given systemically, the penicillin would not pass in any appreciable amount into the theca. It was also known that patients who were given penicillin systemically in adequate doses would still have relapses of meningitis. Therefore, in answer to Mr. Cawthorne's question, he did not think there was any likelihood, with the present compounds, that systemic treatment would replace intrathecal treatment.

If Mr. Layton would read the opening paper he would find that they had in fact distinguished between the acute and the chronic cases. A chronic focus, where there was a collection of pus or sequestra, ought to be dealt with surgically. However, he was not clear from what had been said whether Mr. Layton would hold his hand in any case or whether he would go ahead and operate on all of them, acute and chronic, as he did in the old days. As far as osteomyelitis of the long bones was concerned surgeons had changed their views very considerably since the advent of penicillin.

Patients who got an attack of pneumococcal meningitis did not seem to become more immune, at any rate not for a long time. Relapses, of which there might be eight or nine in one case, were just as severe as the initial attack. If each attack of meningitis were treated as patiently and energetically as the first, and the surgeon in charge did not lose heart or allow the nurses to lose heart, success would be achieved and the patient would in the end cease to relapse.

There was a great field here for the otologist to work out precisely the degree to which penicillin could help him in the treatment of mastoid infection and also in its prevention in cases of otitis media.

not convinced that it is always so. "I have opened", he writes, "the Bodies of many that have died of this Disease in whom the Lungs were free from any Ulcer yet they were set about with little Swellings or stones or sandy matter throughout the whole . . . wherefore a Phthisis is better defined: 'That it is a withering away of a whole Body arising from an ill formation of the lungs'." He corrects the common error, spread among the Medical Profession, from the time of Hippocrates himself: "For what is vulgarly inferred that Phlegm falling from the Head into the Lungs and abiding there putrifies is most commonly the cause of Phthisis . . . we have previously intimated to be altogether erroneous." This upsetting of a long-established belief, on the ground, no doubt, of post-mortem examinations carefully performed, was a real service to our knowledge, made through the sagacity of Willis. Harvey's discovery appears to have had an influence upon the thoughts of this man. "This kind of Cough", he writes, "one which is catarrhal in as much as the Lympha, having passed through the Mass of the Blood, is deposited in the Lungs by the Arteries." . . . As one of the Oxford group of medical workers, he must, of course, have associated with Boyle, Hook, and others. With Lower he was an intimate friend.

Thomas Sydenham (1624-1681) we know, was a close friend of Boyle; in fact there is a letter of his to Boyle talking familiarly with the latter about the trials and occasional successes of medical practice and especially the existence of certain doctors of the baser sort! "I have the happiness", he says, "of curing my patients; at least of having it said concerning me that few miscarry under me; but I cannot brag of my correspondency with some others of my Faculty. Though yet, in taking fire at my attempts to reduce practice to a greater easiness, plainness, and in the mean time letting the Mountibank at Charing Cross pass unrailled at, they contradict themselves and would make the world believe I may prove more considerable than they would have me." Sydenham is too great and too familiar a figure to treat of in a short paper like this but there is one anecdote of his methods which I *must* quote here as an instance of his reduction of medical practice to a "greater easiness and plainness". He was called to see a gentleman who had been subjected by some other physician to a very lowering treatment and who was found by Sydenham to be "in a pitiful state of hysterical upset" occasioned, as he thought, "By the patient's long illness; partly by previous evacuation and partly by emptiness". His remedy was simple: "I therefore ordered him a roast chicken and a pint of Canary."

Sydenham's contribution to the Study of Consumption is contained in a fragment of his papers found after his death and entitled *De Phthisi*. In this short note, in which he talks of the causes of consumption and which still gives evidence, to me at least, of a definite suggestion of the influence of Harvey's work, he speaks very effectively, for that time, as to the management and of the treatment of the disease, and mentions, too, a little of the epidemiology of phthisis as it then occurred around London. "To this disease are most incident men and women from puberty to the state of life; i.e. from 15 to 25; . . . By a peculiar infelicity of our Air none are more subject to it than the inhabitants of London." He says that "the *kinds* of Phthisis differ altogether in their causes and consequently require different cures". The varieties of phthisis he describes are as follows: (1) "For a little before the Winter Solistice upon the first approach of some bitter cold, almost everyone coughs by the transpiration being suddenly checked . . . some by ill-management keep these coughs so long that the lungs are at length much debilitated by the innumerable successions that are constantly made by the act of coughing. The lungs being thus repleated with pus, from them flow purulent streams into the blood which causes a sort of putrid fever whose access is towards morning by a profuse and weakening sweat." "Lastly towards the completing of this tragedy comes on a *diarrhœa colliquitiva* . . . and then death is at hand. . . . though the Patient has all this while a serenity of mind and flatters himself with an opinion of recovery which is usual in this disease until the very last."

(2) "The second sort of consumption is laid in quite contrary season, viz. 'in the beginning of summer; for about this time a spitting of blood often happens to such young men whose blood is weak but hot and sharp, after violent exercises or a debauch of drinking'."

(3) "A third sort happens at the end of a fever, when the febrile matter is discharged upon the lungs and so, in the place of the essential fever, there succeeds a hectic . . . and, not long after, a *diarrhœa lethalis*; for they soon die of this sort of Phthisis." This division of phthisis into three does not, it seems to me, speak very well for the theoretical conceptions of Sydenham but he becomes his practical self again in his insistence upon riding as a cure for certain cases of the disease. "I am sure that if any physician had a remedy for the curing of phthisis of equal force with this of riding, he might easily get

He was pressed by medical friends to write a book on phthisis both from his own experiences and from his observations on others. His *Theatri Tabidorum Vestibulum* was the result and must have been written in or about the years 1653 and 1655. It was intended to be the introduction to a larger work but the disease, in its insistent way, called him and he was obliged to go! He died of consumption in 1655.

His book insists on the closest examination of the sputum as a guide to what is going on in the lungs. "That the Pulmonary Artery with its Divarications receives the Blood's Recrements and thence detaches them into the Branches of the Wind-pipe is a matter quite out of Dispute." He insists on the following as the varieties of sputum to be met with: "Bloody and brackish Excretions brought up by spitting at certain periods; that is, the Morning and Afternoon; more frequent Spitting and Hawking; the interception of the cutaneous and other Excretions; Globulous Spittle rolled up like Hail Stones, a dirty and ash-coloured and purulent Spittle." It is sad to remember that he must have observed all these features of the sputum in himself as well as in others. Perhaps, however, he may have enjoyed the hope which so often encourages as a part of a phthisical attack. "If by the assistance of Art the Spittle, which was variegated, be brought to one Colour; if from muddy it becomes depurated; if from an unequal Consistence it becomes smooth; if from saline, insipid; if from Stinking, without any Scent; and if, lastly, it comes Easily; it is a Sign of Recovery." He was a firm believer in the hereditary nature of the disease as often met with. Perhaps his father, John Bennet of Raynton in Somerset, may have suffered from it or his mother or some other near relative! Of this we know nothing. But he speaks of an infectious propinquity as a probable cause. "Nor are therè wanting", he says, "such as bring their constitutions with them into the World, whose Parents have died Valetudinarians or Consumptives, abounding with a cold or an immature Semen or, perhaps, over-run with an Acrimonious Heat." He goes on to quote the Hippocratic thesis at this point. "These persons"—here he refers to the offspring of the tuberculous—"have sharp shoulders which are therefore called *πτερυγίδες* (wing-like), a contracted Thorax, a narrow and low Chest, a long, thin neck, a flaccid Tone of the parts about the Breast and a very flabby Contexture of the Muscles all over the Body." It is not strange that these signs, so common in young persons exposed to contact with infection, should have been noted, as they so often were, as *causes* of consumption, but Bennet notices them as *symptoms* of the disease in those born of "valetudinarians or Consumptives" and thus is far in advance of his time.

He lays great stress on the six "Non-naturals" as he calls them which were then so much bound up with the treatment of consumptives. Richard Morton also mentioned them as well as Benjamin Marten. They are: prudence in choosing one's meat and drink; sleeping in the forepart of the night; the taking of moderate exercise; the laying aside of care, melancholy and poring thoughts; the avoidance of strong purges; and, lastly, the breathing of a pure air uncontaminated with the smoke of coals. Bennet seems to regard them as too well known to be worth putting down in detail, though Richard Morton did so, but he describes carefully how to *use* them. Why they should be called the "non-naturals" is a puzzle to me. All six seem to be natural to the last degree. But they are called "the non-naturals" both by Bennet, Morton and Marten and must have been quoted from some important and earlier work; possibly from Von Helmont or from Sylvius de la Boë! At all events great importance was attached to them in Bennet's time. His own conclusion as to exercise may be quoted: "The most proper times for Exercise are farthest from eating and drinking. . . . In the Motion and Measure of such things, both Reason and the Physician dictate that they ought to be equal to the Strength and the Times destined by Nature." He says, too, that "more brisk Exercise that opens the muscles of the Brest may sometimes be advised to those whose organs of Respiration are of a relaxed Tone and cold Temperature; as drawing the Bow, Exercise of the Pikes, etc."

Thomas Willis (1621-1675) of Christ Church in Oxford and the Sidley Professor of Natural Philosophy did not write a special book about tuberculosis but gives a valuable chapter to the subject in his *Practice of Physic*, printed by H. Clark for Dring, Harper and J. Leigh, in 1684. Born at Great Bedwin in Wiltshire, the son of a farmer who was killed, as an old man, in the Siege of Oxford, in 1646, he was evidently a loyalist and served throughout the troubles as a soldier in the University Legion. He graduated in Oxford as a B.M. and undertook practice there in 1646, the year of his father's death. He afterwards became famous as the describer of the Circle of Willis. His chapter on tuberculosis begins as follows: "Of all the Diseases of the Brest, a Phthisis or Consumption by right claims the first Place for there is none more frequent or more difficult to cure; moreover the other Affects of the Thorax being ill or not at all Cured lead into this, as lesser Streams into a Great Lake, and so ending in a Phthisis, lose both their Natures and ancient Names." He quotes the common belief that the disease is essentially an ulcer of the lungs but is

of convinced that it is always so. "I have opened", he writes, "the Bodies of many that have died of this Disease in whom the Lungs were free from any Ulcer yet they were set out with little Swellings or stones or sandy matter throughout the whole . . . wherefore a Phthisis is better defined: 'That it is a withering away of a whole Body arising from an ill formation of the lungs.'" He corrects the common error, spread among the Medical Profession from the time of Hippocrates himself; "For what is vulgarly inferred that Phlegm falling from the Head into the Lungs and abiding there putrifies is most commonly the cause of Phthisis . . . we have previously intimated to be altogether erroneous." This upsetting of a long-established belief, on the ground, no doubt, of post-mortem examinations carefully performed, was a real service to our knowledge, made through the sagacity of Willis. Harvey's discovery appears to have had an influence upon the thoughts of this man. "This kind of Cough", he writes, "one which is catarrhal in as much as the Lympha, having passed through the Mass of the Blood, is deposited in the Lungs by the Arteries." . . . As one of the Oxford group of medical workers, he must, of course, have associated with Boyle, Hook, and others. With Lower he was an intimate friend.

Thomas Sydenham (1624-1681) we know, was a close friend of Boyle; in fact there is a letter of his to Boyle talking familiarly with the latter about the trials and occasional successes of medical practice and especially the existence of certain doctors of the baser sort! "I have the happiness", he says, "of curing my patients; at least of having it said concerning me that few miscarry under me; but I cannot brag of my correspondence with some others of my Faculty. Though yet, in taking fire at my attempts to reduce practice to a greater easiness, plainness, and in the mean time letting the Mountbank at Charing Cross pass unrailed at, they contradict themselves and would make the world believe I may prove more considerable than they would have me." Sydenham is too great and too familiar a figure to treat of in a short paper like this but there is one anecdote of his methods which I must quote here as an instance of his reduction of medical practice to a "greater easiness and plainness". He was called to see a gentleman who had been subjected by some other physician to a very lowering treatment and who was found by Sydenham to be "in a pitiful state of hysterical upset" occasioned, as he thought, "By the patient's long illness; partly by previous evacuation and partly by emptiness". His remedy was simple: "I therefore ordered him a roast chicken and a pint of Canary."

Sydenham's contribution to the Study of Consumption is contained in a fragment of his papers found after his death and entitled *De Phthisi*. In this short note, in which he talks of the causes of consumption and which still gives evidence, to me at least, of a definite suggestion of the influence of Harvey's work, he speaks very effectively, for that time, as to the management and of the treatment of the disease, and mentions, too, a little of the epidemiology of phthisis as it then occurred around London. "To this disease are most incident men and women from puberty to the state of life; i.e. from 15 to 25; . . . By a peculiar infelicity of our Air none are more subject to it than the inhabitants of London." He says that "the kinds of Phthisis differ altogether in their causes and consequently require different cures". The varieties of phthisis he describes are as follows: (1) "For a little before the Winter Solistice upon the first approach of some bitter cold, almost everyone coughs by the transpiration being suddenly checked . . . some by ill-management keep these coughs so long that the lungs are at length much debilitated by the innumerable succussions that are constantly made by the act of coughing. The lungs being thus repleted with pus, from them flow purulent streams into the blood which causes a sort of putrid fever whose access is towards morning by a profuse and weakening sweat." "Lastly towards the completing of this tragedy comes on a *diarrhœa colliquativa* . . . and then death is at hand. . . . though the Patient has all this while a serenity of mind and flatters himself with an opinion of recovery which is usual in this disease until the very last."

(2) "The second sort of consumption is laid in quite contrary season, viz. 'in the beginning of summer; for about this time a spitting of blood often happens to such young men whose blood is weak but hot and sharp, after violent exercises or a debauch of drinking'."

(3) "A third sort happens at the end of a fever, when the febrile matter is discharged upon the lungs and so, in the place of the essential fever, there succeeds a hectic . . . and, not long after, a *diarrhœa lethalis*; for they soon die of this sort of Phthisis." This division of phthisis into three does not, it seems to me, speak very well for the theoretical conceptions of Sydenham but he becomes his practical self again in his insistence upon riding as a cure for certain cases of the disease. "I am sure that if any physician had a remedy for the curing of phthisis of equal force with this of riding, he might easily get

what he pleased; in a word I put very many people upon this exercise in order to cure a consumption and I can truly say I have missed the cure of very few."

At a time when riding was universal and when practically nobody was unfamiliar with it, this kind of advice was probably the best by far that could be given to those cases in a fit state to get on a horse instead of sitting at home too depressed to take any kind of exercise. I can imagine that it saved many—and probably got added force from the numerous persons who suffered from chronic coughs unconnected with consumption and were, nevertheless, called phthisical.

We have already given descriptions of the works of Richard Morton and of Benjamin Marten in the *Proceedings* of the Section, but we must add a few words here.

At first a Clergyman, Richard Morton, was finally made to transfer to medicine by the Act of Uniformity which, in the words of Trevelyan, "turned adrift without compensation 2,000 of the clergy who could not record their 'unfeigned consent and assent' to everything" that the new Prayer Book contained. This was, perhaps, fortunate for the medical profession as his great book, *Phthysiologia*, is one of the only works on the subject of consumption of conspicuous merit dating from the seventeenth century. We quote his own words to describe the "Six Non-Naturals" referred to above in speaking of Christopher Bennet: "Let them also heed not to eat too much food though it be such as to afford a good Juice, as also that they do not drink too much Wine or Strong Liquors, Secondly, let them sleep in the fore part of the Night: but let them avoid sleeping in the day-time, yea, and sleeping too long in the morning; because much sleep is wont to retain and heap up a great load of Humours in the Habit of the Body. Thirdly, let them every day use moderate Exercise and Rubbing for a good while together to fetch out the dispirited Humours from the Habit of the Body by the Pores of the Skin. Fourthly, let them strictly avoid all strong Purges; for as much as they not only weaken Nature but also, by putting the Blood into too great a motion with their sharp Particles, they make it grow acrid and hot and bring it into a more serious and collicquative state; upon which a Catarrh and a Consumption are wont to follow. Fifthly, let the Patient by all lawful ways industriously lay aside Care, Melancholy and all poring of his Thoughts as much as ever he can and endeavour to be cheerful. For I have observed that a Consumption of the Lungs has had its origin from long and grievous Passions of the Mind. Sixthly, let the Patient enjoy an open, fresh and kindly air and such as is free from the Smoke of Coals, etc." Of Benjamin Marten it may be justly said that he had the wonderful imagination of a Villemain or a Koch without the facilities that came to the hands of these Masters through the strivings of Pasteur. His *New Theory of Consumptions* was one of the very best books on the subject of phthisis even apart from its almost magical adumbration of the essential cause; but it fell into complete disuse chiefly because its merits, though understandable to every medical student to-day, were then obscurely hidden from the medical profession by a whole host of dyscrasie, dispositions and other vestiges of our ancient faiths, which had to be pulled down before the rich harvest of truth could develop in its full splendour. But he had the vision! We must, I think, admit him to the position of a great Dreamer whose ideas led quietly onwards to the conception of tuberculosis in our possession at the present time.

Intravenous Pentothal as the Sole Anæsthetic for Tonsillectomy

By MAJOR CLIFFORD HAYES, R.A.M.C.

THIS report describes 82 consecutive unselected anæsthetics for the dissection of tonsils, using intravenous sodium pentothal as sole anæsthetic, without the use of any artificial air-way during operation, using the Boyle-Davies' gag only. One case had, in addition, a partial repair of a cleft palate. A large proportion of the patients were Guardsmen and of a very robust physique, with extremely difficult and adherent tonsils or remnants, one, for example, giving a history of 17 previous attacks of quinsy. Since the completion of the original series approximately another 60 cases have been anæsthetized by the same method with similar results, though no exact record of these cases was kept.

The series was originally begun merely out of interest, in fact with anticipation of failure. The surgeon, however, became so impressed with the results that he insisted on completing the series and will now use no other method of anæsthesia. Undoubtedly the main advantages are surgical but the anæsthetist's task is very much simplified, and the anæsthetic time is reduced by the length of the induction period which is shortened to a few seconds. No references are quoted in this series as it was completed overseas and the literature was not available.

Technique.—No special pre-operative preparation was used, nothing being allowed by mouth for four hours before operation. Opoidine 1/3 grain and scopolamine 1/150 grain in 1 c.c. ampoules was given by hypodermic injection at least one hour beforehand.

In the first 25 cases a 10% solution of pentothal was used with syringe and needle. In the remaining cases a 5% solution was used and given by means of a graduated vessel suspended four feet above the arm, rubber tubing, spring clip and a large bore needle (the giving needle of the Army Blood Transfusion Set). The solution was allowed to enter the vein by gravity only. The basic technique was the same for all cases, and the results and dosage appeared identical.

The operations were performed on a standard portable operating table. During induction the patient lay flat with a pillow beneath the head. The induction dose was 0.6 to 0.8 gramme of pentothal, depending on the type of patient and his response to premedication. When anæsthesia was established the pillow was removed, a sandbag inserted under the shoulders and the relaxation of the jaw tested. If this appeared satisfactory, the Boyle-Davies' gag was inserted. Otherwise, a further 1 to 4 c.c. (0.05 to 0.2 gramme) was injected first, depending on the degree of muscular rigidity persisting. In four cases, over 1 gramme was required to produce adequate relaxation of the jaw.

Maintenance dosage was based almost entirely on the depth of respiration, phonation in the smallest degree also being regarded as an indication for further pentothal. The first sign of involuntary lightening of the anæsthesia was almost always phonation, but gagging was occasionally noticed by the surgeon before phonation and was dealt with in the same way. Each additional dose was 1 to 4 c.c. (0.05 to 0.8 gramme) and, when possible, the surgeon refrained from stimulating the patient until after the resulting hyperpnœa, though this was not important except in marked lightening of the anæsthesia.

This hyperpnœa was seen in every case following repeat or maintenance doses except two in which pentothal buffered with sodium carbonate as on issue to the U.S. Army M.C. was employed. It was invariably followed by a short apnœa of 5 to 20 seconds. In 14 cases this apnœa was of longer duration due to slight over-dosage and was thus accompanied by slight cyanosis. This was quite transient and was in every case relieved by the resumption of normal respiration before any treatment could be instituted. Neither artificial respiration nor coramine was needed on any occasion.

A small stream of oxygen was run through the side tube of the Boyle-Davies' gag in the last 50 cases and this procedure was continued until the surgeon was satisfied with the hæmostasis, when the gag was replaced by a Water's metal air-way. The sandbag was then removed and a low pillow placed beneath the head. The patient was then returned to the ward and placed on his side. In none of the cases was a sucker employed and no need for one was experienced.

Total dosage has been 1.2 to 2.4 grammes, the average dose being 1.6 grammes. Operation time has been 12 to 35 minutes, the average time being 20 minutes.

A post-nasal swab was inserted as a routine by the surgeon except in the very early cases. This procedure was adopted following one case in which spasm occurred post-operatively. This was found to be due to blood which had pooled in the nose during operation and had run down into the larynx when the head was moved.

On two occasions, while awaiting complete hæmostasis, the vocal cords were examined by lifting the epiglottis, touching with a swab and thus inducing a spasm. This was completely relieved by a further dose of 0.2 gramme of pentothal.

Complications.—During the operation, when in 2 early cases a tongue plate of insufficient size was used, there was some difficulty in maintaining the air-way. In no other case was any difficulty with the air-way encountered, and indeed the ease of respiration has been greater by this method than with a large bore endotracheal catheter, since it has been so much quieter.

There is little need to stress that any foreign material entering the larynx will cause laryngeal spasm. When such a spasm was induced deliberately by direct stimulation of the larynx, it was found that both the removal of the stimulus, and the administration of further pentothal, were needed to relieve it.

On one occasion while the normal operating table was under repair, five operations were performed using a stretcher on trestles. In one patient the head became elevated, owing to the "give" in the stretcher and some coughing occurred in the early stages, until the cause was recognized and the surgeon took the necessary extra care in mopping up the blood. Then normal anaesthesia was re-established by the administration of a further 0.2 gramme of pentothal.

Post-operative respiratory spasm occurred in 6 cases and caused some degree of coughing. These all showed some cyanosis which was lessened within three minutes by the removal of the air-way. There was occasional thrombosis of the vein used for injection, and in one case a phlebitis, which lasted for five days. All these occurred following the 10% solution. These were the only post-operative complications encountered and spasm did not appear to be any worse than that seen in tonsillectomies anesthetized by other methods, and had disappeared within ten minutes.

The immediate post-operative course was remarkably improved, no patient requiring more than one dose of morphine $\frac{1}{4}$ grain and all except the 6 mentioned above sleeping quietly as in normal sleep, and eating normal meals as "up" patients in hospital "blues" on the day after operation. There was no post-operative nausea or vomiting.

Thus laryngeal stimulation and underdosage appear to be the main pitfalls as inadequate depth will cause spasm in the absence of laryngeal stimulation.

Advantages.—Induction is extremely pleasant from the point of view of the patient. The surgeon reports that he found the diminution in oozing quite striking and comparable with local anaesthesia without the concomitant œdema. The oozing was even less in those cases where oxygen was run through the side tube of the Boyle-Davies' gag.

Breathing is quiet and effortless. The minor degrees of trauma to nose and larynx occasionally inseparable from the most careful intubation are completely avoided.

The protective laryngeal reflex should persist, thus giving ample warning of the aspiration of blood by the onset of stridor. The pharyngeal reflex must be abolished this results in lax pillars with obvious advantage. Should any foreign material stimulate the larynx, control can be regained almost at once by the removal of the stimulus and the exhibition of further pentothal. With a method of anaesthesia which abolishes the laryngeal reflex this "warning-note" is absent and instant control is impossible.

The post-operative course is markedly improved especially in its early stages. (One nursing sister in the series on her first post-operative morning reported that she was far more comfortable than during her previous attack of tonsillitis.)

SUMMARY

This appears to be a safe form of anaesthesia for dissection of tonsils, offering the advantages of ease of operation for the surgeon, resulting from the effortless respiration, and complete lack of congestion. It is pleasant for the patient and offers a smooth recovery with no vomiting. The immediate post-operative period is thus much improved. It is not suggested that this method is ideal for all purposes; for the novice it is perhaps quite useless. On the other hand, it offers many advantages to the surgeon and anaesthetist provided that the latter is familiar with the minor variations in depth of anaesthesia under pentothal.

I am indebted to Major J. V. Broad, R.A.M.C., who performed all the operations in the original series for his unfailing co-operation and very many helpful suggestions; also to the Adviser in Anaesthetics, C.M.F., at that time, for much encouragement and helpful criticism, and to the Officer Commanding the hospital for his co-operation.

Personal Experience of Bronchoscopy

By GEOFFREY ORGANE, M.D.

I HAVE learnt from a personal experience of bronchoscopy many lessons which have helped me in my work.

No premedication was used that the experience might be savoured to the full and its lack seemed no disadvantage.

Anæsthetic technique.—I used amethocaine 2% in an oral spray at intervals from forty-five to fifteen minutes beforehand. It was not unpleasant and produced a definite effect on the pharynx.

This was followed by a lozenge containing 1 grain (65 mg.) amethocaine. The flavour was most unpleasant and could well be improved. The first two swallows of saliva produced retching. Salivation was profuse; this is preferable to the dryness following atropine or scopolamine—ulceration is said to have occurred where the half dry lozenge has stuck to the palate. Anæsthesia of the pharynx, tongue and lips appeared to be complete within five minutes.

In the theatre, swabs soaked in the same amethocaine solution were applied twice to each pyriform fossa. This seemed unnecessary, and the unguarded tip of the Krause's forceps on the left side produced discomfort and an attack of coughing. My tongue was held in a gauze swab—a surprisingly painful procedure, which I have since abandoned.

The intratracheal injection (through the cricothyroid membrane) of a further 2 c.c. was made in the sitting position with a fairly large needle (about size 12). There was a sensation of cold as the solution impinged on the posterior wall of the trachea, followed by uncontrollable coughing as it trickled down towards the carina. My own practice is to use a fine hypodermic needle; I feel that, with a small puncture hole, there is less chance of surgical emphysema or of cellulitis of the neck. With a larger needle the injection can be completed more rapidly and it should, therefore, be possible to withdraw it before coughing starts, so lessening the risk of breakage.

Bronchoscopy.—Passage of the bronchoscope over the dorsum of the tongue and its elevation towards the larynx produced the only discomfort of the operation, and this was only trivial. There was a sensation of stretching of the fauces which disappeared after the manipulation. There was a slight tickling feeling as it passed through the cords. As the bronchoscope approached the carina and entered each main bronchus there was uncontrollable coughing, eased in a matter of seconds by spraying local anæsthetic down the bronchoscope. The sucker was used once, producing no appreciable sensation. A gauze swab introduced into the left main bronchus caused a sense of obstruction, immediately relieved by breath-holding. The telescope down the right side increased the resistance to breathing, and down the left side produced a tickle which was relieved by breath-holding.

The presence of the bronchoscope produced no sensation whatever. Coughing through a bronchoscope feels like normal coughing.

There was no sense of pressure on the teeth. The available space between bronchoscope and teeth was appreciably increased by full hyperextension of the head on the neck. After some minutes there was aching in the temporomandibular joints.

Cerebral effects.—Cerebral stimulation was marked, with euphoria and garrulousness. Cerebral efficiency, as tested on the *Daily Telegraph* crossword puzzle, was much increased. It is not possible to attribute this to absorption of amethocaine as I afterwards discovered that, unknown to the surgeon or to myself, 100 mg. cocaine had been used in the endobronchial spray.

Post-operative course.—Anæsthesia wore off rapidly. I drank water within twenty minutes without untoward effect. At tea one hour after I could distinguish easily between the flavours of white and brown bread. There was a slight soreness in the chest during recovery, and an irritating non-productive cough. A moderate sore throat persisted for three days.

Comments.—Bronchoscopy under local anæsthesia at the hands of an expert produces only trivial discomfort—I much prefer it to a visit to the dentist!

Premedication is unnecessary and would be best confined to opiates to avoid the excessive dryness associated with atropine or scopolamine.

Local anæsthetics sprayed vigorously down the throat and nose during inspiration produce no significant anæsthesia below the vocal cords. They must be introduced directly into the trachea. The amethocaine lozenge is extremely unpleasant and its routine use before anæsthesia is an imposition on the patient. It could be improved by the introduction of flavouring materials. It is entirely effective and no further application of anæsthetic to the pharynx is needed. If the tongue is to be held forward, this should be done by the patient himself.

A post-nasal swab was inserted as a routine by the surgeon except in the very early cases. This procedure was adopted following one case in which spasm occurred post-operatively. This was found to be due to blood which had pooled in the nose during operation and had run down into the larynx when the head was moved.

On two occasions, while awaiting complete hæmostasis, the vocal cords were examined by lifting the epiglottis, touching with a swab and thus inducing a spasm. This was completely relieved by a further dose of 0.2 grammes of pentothal.

Complications.—During the operation, when in 2 early cases a tongue plate of insufficient size was used, there was some difficulty in maintaining the air-way. In no other case was any difficulty with the air-way encountered, and indeed the ease of respiration has been greater by this method than with a large bore endotracheal catheter, since it has been so much quieter.

[April 8, 1946]

DISCUSSION ON DENTAL STRUCTURE AND DENTAL CARIES

Mr. E. B. Manley: I have been asked to discuss very briefly the dental structure that may be laid down within the pulp both in response to caries and also to other injuries brought about indirectly as a result of operative procedures concerned with the treatment of caries.

This is to a large extent in conformity with the broad conception of Thoma (1941) concerning dental caries. He draws attention to the fact that although it may affect clinically the calcified structures it also invokes a protective reaction that involves the entire organ. He not only regards the disease as attacking the tooth from without but he also includes the effect of the reaction that takes place from within to protect the tooth from injury and resist the invasion of bacteria.

The clinical picture of caries should include both the defence forces as well as the attacking forces. Examination of serial sections of the pulp *in situ* under carious lesions of varying degrees of severity is instructive.

It has been stated that the natural enemies of the dental pulp are bacteria and thermal changes. To these should be added two unnatural enemies, traumatic and chemical irritation, both of which may be evoked and exert their influence during the surgical treatment of dental caries. The recuperative powers of the human pulp are regarded by many as being very limited, but that this organ does in fact possess great powers of recovery can now be demonstrated with some degree of certainty. The pulp consists of undifferentiated connective tissue with a layer of highly differentiated cells, the odontoblasts. The undifferentiated connective tissue must, like all other vascular tissues of the body, have a normal mechanism of defence. This means of defence, however, is handicapped to a certain extent owing to the anatomical environment of the pulp together with the lack of a collateral circulation. In addition, however, the power to lay down calcific material in one form or another is the most potent factor of all the defence measures of the pulp. The nature of this "calcified tissue of repair" has been investigated and described in detail by E. W. Fish (1939).

The object of this communication is to illustrate from a physiological point of view some conditions under which this material can be laid down and also to refer to certain factors, other than infection, that may inhibit the process. A most severe form of injury will be used as an example, i.e. traumatic exposure of the pulp brought about during cavity preparation. Both experimental and clinical cases will be shown.

Experimental.—Premolar teeth whose removal was required for orthodontic purposes were chosen. With the use of a slowly revolving bur, cavities were cut on the gingival third of the buccal surface and a small exposure of the pulp obtained. During the cutting of the cavity the powdered fragments of dentine were carefully collected and then replaced over the exposed surface of the pulp. The cavity was then sealed with zinc-oxide clove oil paste. No other form of medication was resorted to. The teeth were extracted and serial sections prepared. One of the results is illustrated in fig. 1. After seven weeks the dentine particles have been carried into the pulp tissue and calcified material laid down around them forming a compact mass of callus in an attempt to seal off the exposed area. The particles of primary dentine and nature of the new-formed tissue is illustrated under high magnification in fig. 2 from a tooth extracted after nine weeks. The powdered dentine appears to act as an organizer and determines the differentiation of the mesenchyme cells into osteogenic cells, thus ensuring a further deposit of matrix (fig. 3). Experiments were also carried out in which the exposed surface of the pulp was touched with phenol prior to covering with zinc-oxide clove oil paste. The result is illustrated in fig. 4. A large area of pulp tissue has been completely destroyed and no new deposit of matrix can take place around the fragments of dentine which passed into the pulp at the time of exposure. The vitality of the pulp tissue was not impaired by the use of hydrogen peroxide.

Clinical (Case I, figs. 5, 6 and 7).—A traumatic exposure of the pulp horn of an upper third molar occurred during cavity preparation in January 1940. The exposed surface was covered with zinc-oxide clove oil paste without other medication of any kind. After a period of two weeks the permanent restoration was completed. The tooth was extracted in February 1945, after five years following the removal of the lower third molar. Fig. 5

Coughing during bronchoscopy may not be controllable by the patient in spite of exhortation and is rapidly relieved by further local anæsthetic sprayed down the bronchoscope. The cough sometimes found on introduction of the telescope in an otherwise quiet patient is probably due to overloading and consequent over-heating of the light bulb. In a difficult case, pressure on the teeth can be reduced by hyper-extension of the head. I have since adopted this position for direct laryngoscopy with advantage. If the patient is instructed to hold his breath before a gauze swab is introduced, one minor discomfort can be eliminated.

It is not necessary to forbid food or drink for more than one hour, at most, afterwards.

Recommendations.—There are many methods of anæsthesia available for bronchoscopy in adults, including the sledge-hammer blow of curare. Where general anæsthesia is to be used, I would advise thiopentone in sufficient dose to abolish consciousness, preceded by full local anæsthesia. The method of choice would seem to be premedication with opiates only; a lozenge containing amethocaine or nupercaine to be sucked ten minutes beforehand, or, better, a gargle of 2% amethocaine, with strict watch to see that none is swallowed; the application of local anæsthetic to the vocal cords by injection of, say, 2 c.c. 2% amethocaine through a curved laryngeal cannula passed well down over the dorsum of the tongue with the patient sitting; the introduction of 2 c.c. more into the trachea through the cricothyroid membrane or the trachea itself, or by a laryngeal cannula passed between the cords under indirect vision (direct laryngoscopy is uncomfortable); this to be supplemented by further local anæsthetic sprayed down the bronchoscope whenever indicated.

Luminous Indicators

[SHORT PRELIMINARY REPORT]

Dr. A. H. Galley said that the present use of luminous indicators on anæsthetic machines was limited to apparatus manufactured by Messrs. Coxeter and consisted of:—

- (a) A luminous plaque fixed behind Rotameter flowmeters.
- (b) Luminous handle on Coxeter-Mushin carbon dioxide absorber unit.

Dr. Galley suggested and demonstrated the following extensions of use:—

- (1) *Illumination of Flowmeters*
 - (a) Separate illuminated strip behind each flowmeter thus obviating bright luminous strips between each flowmeter and enhancing the illumination coming through each flowmeter.
- (2) *Illumination of Oxygen Controls*
 - (a) Luminous indicator hand on cylinder pressure gauge.
 - (b) Luminous control-knob for low pressure oxygen supply.
 - (c) Luminous tap (or button) for emergency oxygen flood.
- (3) *Illumination of Interior of Trilene Bottle*
Luminous semicircular plaque (with circular base) to fit on trilene bottle and illuminate interior.
- (4) *Illumination of Respiratory Movements*
 - (a) Luminous "snood" (or painted stripes) on rebreathing bag.
 - (b) Luminous brooch to pin on chest and indicate thoracic movements.

Dr. Galley said that there was a serious need for improved conditions when administering anæsthetics in complete darkness in the X-ray departments of hospitals. Although fatalities were rare there had been several instances of anoxia from the running out of oxygen supply with subsequent mental symptoms lasting in one case for over six months and retarding the development of a child. The above devices and suggestions would eliminate all possibility of anoxia; the supply of oxygen could be estimated at a glance, the controls found and manipulated without fumbling, and by means of the luminous brooch and illuminated rebreathing bag the anæsthetist could be assured of a satisfactory tidal exchange taking place. The flashing of torches was obviated, a practice which always upset the accommodation of eyesight of surgeon or radiologist.

The speaker demonstrated his apparatus and showed how fluorescent indicators could be used which would shine in different colours when subjected to light from an ultra-violet light bulb which gave off no visible rays. Various improvements in the indicators were under review, e.g. the use of a coatée embroidered with criss-cross lines of luminous plastic thread and which would replace the luminous brooch. Before final publication of these devices the British Standards Institution would be consulted with regard to standardizing the fluorescent colours used and associated with the various flowmeters (e.g. nitrous oxide could not be indicated by black luminous paint as no such entity existed—lemon yellow was used at present).

DISCUSSION ON DENTAL STRUCTURE AND DENTAL CARIES

Mr. E. B. Manley: I have been asked to discuss very briefly the dental structure that may be laid down within the pulp both in response to caries and also to other injuries brought about indirectly as a result of operative procedures concerned with the treatment of caries.

This is to a large extent in conformity with the broad conception of Thoma (1941) concerning dental caries. He draws attention to the fact that although it may affect clinically the calcified structures it also invokes a protective reaction that involves the entire organ. He not only regards the disease as attacking the tooth from without but he also includes the effect of the reaction that takes place from within to protect the tooth from injury and resist the invasion of bacteria.

The clinical picture of caries should include both the defence forces as well as the attacking forces. Examination of serial sections of the pulp *in situ* under carious lesions of varying degrees of severity is instructive.

It has been stated that the natural enemies of the dental pulp are bacteria and thermal changes. To these should be added two unnatural enemies, traumatic and chemical irritation, both of which may be evoked and exert their influence during the surgical treatment of dental caries. The recuperative powers of the human pulp are regarded by many as being very limited, but that this organ does in fact possess great powers of recovery can now be demonstrated with some degree of certainty. The pulp consists of undifferentiated connective tissue with a layer of highly differentiated cells, the odontoblasts. The undifferentiated connective tissue must, like all other vascular tissues of the body, have a normal mechanism of defence. This means of defence, however, is handicapped to a certain extent owing to the anatomical environment of the pulp together with the lack of a collateral circulation. In addition, however, the power to lay down calcific material in one form or another is the most potent factor of all the defence measures of the pulp. The nature of this "calcified tissue of repair" has been investigated and described in detail by E. W. Fish (1939).

The object of this communication is to illustrate from a physiological point of view some conditions under which this material can be laid down and also to refer to certain factors, other than infection, that may inhibit the process. A most severe form of injury will be used as an example, i.e. traumatic exposure of the pulp brought about during cavity preparation. Both experimental and clinical cases will be shown.

Experimental.—Premolar teeth whose removal was required for orthodontic purposes were chosen. With the use of a slowly revolving bur, cavities were cut on the gingival third of the buccal surface and a small exposure of the pulp obtained. During the cutting of the cavity the powdered fragments of dentine were carefully collected and then replaced over the exposed surface of the pulp. The cavity was then sealed with zinc-oxide clove oil paste. No other form of medication was resorted to. The teeth were extracted and serial sections prepared. One of the results is illustrated in fig. 1. After seven weeks the dentine particles have been carried into the pulp tissue and calcified material laid down around them forming a compact mass of callus in an attempt to seal off the exposed area. The particles of primary dentine and nature of the new-formed tissue is illustrated under high magnification in fig. 2 from a tooth extracted after nine weeks. The powdered dentine appears to act as an organizer and determines the differentiation of the mesenchyme cells into osteogenic cells, thus ensuring a further deposit of matrix (fig. 3). Experiments were also carried out in which the exposed surface of the pulp was touched with phenol prior to covering with zinc-oxide clove oil paste. The result is illustrated in fig. 4. A large area of pulp tissue has been completely destroyed and no new deposit of matrix can take place around the fragments of dentine which passed into the pulp at the time of exposure. The vitality of the pulp tissue was not impaired by the use of hydrogen peroxide.

Clinical (Case I, figs. 5, 6 and 7).—A traumatic exposure of the pulp horn of an upper third molar occurred during cavity preparation in January 1940. The exposed surface was covered with zinc-oxide clove oil paste without other medication of any kind. After a period of two weeks the permanent restoration was completed. The tooth was extracted in February 1945, after five years following the removal of the lower third molar. Fig. 5

FIG. 1 ($\times 20$).—Traumatic exposure, experimental. M.: Mass of calcific material laid down around particles of dentine. After seven weeks.

shows that complete recovery had taken place, the exposed area being walled off by the deposition of calcific material around some fragments of dentine which had been unavoidably pushed into the pulp tissue by the revolving bur. Fig. 6, of higher magnification, illustrates the dentine fragments embedded in the new matrix and unabsorbed after five years. Fig. 7 shows irregularly formed tubular secondary dentine at a point furthest from the site of injury and merging into the new-formed structure laid down around the dentine fragments, thus completing the seal. Other clinical cases of traumatic exposure showed that where no medication by irritant drugs had been resorted to and where there was no infection new matrix had been deposited around fragments of dentine which are invariably pushed into the pulp at the moment of exposure. A clinical case where the exposed surface had been touched with a pledget of cotton-wool moistened with phenol is illustrated in fig. 8. No clinical symptoms were manifest, the tooth being extracted after a period of fifteen months following the removal of the corresponding

tooth in the lower jaw. Destruction of pulp tissue with a chronically inflamed area is seen. The pulp tissue has failed to react favourably and no deposition of calcific material has taken place except at the point "A" where a few fragments of dentine have reached a point outside the zone of irritation. Around them a small amount of new tissue has been laid down and become attached to the wall of the pulp chamber.

It is not surprising that no cases of repair were seen following the use of tissue-destroying drugs either experimentally or clinically. In the experimental work on pulp reaction to dental cements it was found that the ability of the pulp to form secondary dentine was impaired and sometimes completely destroyed under cavities filled with cements possessing a high degree of acidity at the time of insertion into the cavity. From a biological point of view it is essential that no irritating drugs be used.

With regard to the question of infection of the pulp: it is very necessary to distinguish between a carious and a traumatic exposure. In cases of carious exposure there will be gross bacterial infection of the pulp and no treatment other than partial or complete removal of the pulp will avail. On the other hand it is inconceivable that the pulp under the lesion described in the first clinical case should not at some period have been subject to irritation through bacterial toxins, and its recovery would lead one to believe that the pulp can tolerate a certain degree of irritation from infective sources. The question of the degree of infection that may be present under a carious lesion can only be assessed clinically at the time of the operation in each individual case.

Our understanding of the changes taking place within the pulp should aid the diagnosis of the condition requiring treatment.

Acknowledgments.—I am indebted to Mr. H. E. Heighway for the clinical material. The technical work of preparing the sections and photomicrographs has been undertaken by Mr. E. B. Brain.

Mr. M. M. Murray: *The structure of enamel and dentine from the chemical and physical aspect.*—Although in respect of its main mineral constituents enamel is fundamentally of the same composition as the inorganic part of dentine and bone yet it is much harder. This hardness is one of the characteristic properties of dental enamel and the question presented itself as to whether, as in the case of steel, which can be hardened by the inclusion of a small proportion of other elements like tungsten, this hardness of enamel might have a similar basis. The elements suspected of causing this hardness were silicon and fluorine. Estimations of these elements in enamel were made; both were present, but the results led, at that time, to no useful deductions. In the case of fluorine, dentine often contained more than the enamel. Later work has shown that a raised fluorine content as found in the enamel of "mottled" teeth alters its properties in many ways, naked-eye appearance, permeability to stains, opacity to soft X-rays (Applebaum, 1936). It appears generally accepted that the enamel of mottled teeth is more brittle than non-mottled enamel, but according to many American investigators it is relatively more immune to caries (Dean, 1940; Armstrong and Brekhuis, 1937). The post-eruptive brown staining often seen in mottled enamel may be an expression of the increased permeability to materials in food or water; it often extends into one-third of the outer depth of the enamel.

The occurrence of organic matter in sound enamel was settled by using improved methods of enamel separation and nitrogen estimation. The amount of protein, calculated from the nitrogen, is about 2%. To what extent the acid-resistant character of enamel could be due to this protein we do not yet know, but it is significant that this protein is probably a type of keratin. Dr. Pincus has worked on the properties of this protein. Although the relative amount of organic to inorganic matter is only 2% by weight, because it has a density of 1.3 and the mineral matter a density of 3, the amount of organic matter (protein) calculated by volume is 5%.

A fairly full chemical analysis of carefully separated enamel and dentine of good, sound, permanent, premolar teeth of children gave the following results (Bowes and Murray, 1935).

TABLE I.

Percentage composition of—					Enamel	Dentine
Ash	95.38	71.09
Nitrogen	0.156	3.43
Calcium	37.07	27.79
Phosphorus	17.22	13.81
CO ₂	1.952	3.176
Fluorine	0.023	0.025
Chlorine	0.364	Nil
Magnesium	0.464	0.835
Ca/P	2.153	2.012

These figures show that the most significant difference between enamel and dentine composition is the degree of calcification or mineralization rather than the type of inorganic material laid down. Careful consideration of the figures shows, however, some differences, for example in the CO_2 and magnesium content and the Ca/P ratio. Robison (1932), pioneer worker on the biochemistry of calcification, spoke of the "bone salt" and considered that all calcification led to the deposition of one salt of constant composition and that this was a form of calcium phosphate containing combined CO_2 and called it "carbonato-apatite". This conclusion is open to criticism because there are certain differences in composition between enamel and dentine of the same tooth, for example the magnesium and carbonate content. In rodents there is a difference in composition between molar and incisor teeth.

An important point for consideration is the actual type of calcium phosphate which forms the main constituent of these structures. One clue to this is the Ca/P ratio. Calcium phosphate $\text{Ca}_3(\text{PO}_4)_2$ gives a ratio of 1.9 and the ratios for enamel and dentine preclude this and point to an apatite structure $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaX}_n$, which gives a ratio of 2.151. Geologists recognize several forms of apatite with X represented by either Cl, F or the OH group, giving $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{Ca}(\text{OH})_n$, which is hydroxy-apatite. Dental structures and bone are composed mainly of this substance, in which a certain amount of the calcium is replaced by magnesium. The form of combination in which the carbonate is present is still not settled. Calculations, based on certain assumptions, made from the chemical analyses gave the following composition for enamel (Bowes and Murray, 1935) (Table II)

TABLE II.—THE COMPOSITION OF ENAMEL FOUND BY CALCULATION USING THE FIGURES GIVEN IN TABLE I.

	%	Ca% in enamel	P% in enamel
Magnesium carbonate...	1.624	—	—
Calcium carbonate...	1.331	0.532	—
Carbonato-apatite...	12.06	4.684	2.178
Fluorapatite...	0.663	0.26	0.122
Chlorapatite...	4.397	1.69	0.786
Hydroxy-apatite...	75.04	29.90	13.90
Sodium...	0.25	—	—
Loss on heating other than CO_2 and H_2O ...	1.837	—	—
Total...	97.202	37.066	16.936
Determined values (see Table I)	—	37.07	17.22

I think it appropriate here to compare the calculated fluorapatite and CO_2 content of mottled and non-mottled enamel and dentine (Bowes and Murray, 1936). The difference

	Fluorapatite content		CO_2 content	
	Enamel	Dentine	Enamel	Dentine
Mottled (Maldon)	0.85%	1.93%	2.35%	3.8%
Non-mottled (London)	0.665%	0.665%	1.95%	3.18%

in fluorapatite is not so great as the difference in properties might lead one to suppose. It may be pointed out here that mottled enamel and dentine contain significantly more carbonate than non-mottled. However, the value of chemical data is limited in ability to give information about actual molecular structure and arrangement and this leads to a consideration of the ultramicroscopic structure.

The interpretations of the microscopic observations on the structure of enamel present some difficulty and I am not competent to discuss this matter. I would, however, like to consider the ultramicroscopic structure as studied by X-ray—crystallographic analysis. This will summarize the work of Thewlis (1940). We collaborated in a combined chemical and physical investigation of dental enamel and various apatites (Glock, Murray and Thewlis, 1939). X-ray analysis gives information on molecular structure and arrangement and greatly extends the information obtained by chemical analysis. To illustrate this point we may compare diamond and graphite; both are composed of carbon, that is chemically identical, but whereas diamond is one of the hardest substances we know, graphite is used as a lubricant. This difference is due to a difference in arrangement of the carbon atoms in the two substances and it is from X-ray analysis that we know why they are different.

A comparison of X-ray diffraction photographs of enamel with those of some typical apatites led to the same conclusions as made from the results of chemical analyses, namely, that enamel is composed principally of hydroxy-apatite. But of greater interest is the arrangement of these apatite molecules. If molecules in any material are arranged in an orderly manner then the material is crystalline. A random arrangement is present in

tooth in the lower jaw. Destruction of pulp tissue with a chronically inflamed area is seen. The pulp tissue has failed to react favourably and no deposition of calcific material has taken place except at the point "A" where a few fragments of dentine have reached a point outside the zone of irritation. Around them a small amount of new tissue has been laid down and become attached to the wall of the pulp chamber.

It is not surprising that no cases of repair were seen following the use of tissue-destroying drugs either experimentally or clinically. In the experimental work on pulp reaction to dental cements it was found that the ability of the pulp to form secondary dentine was impaired and sometimes completely destroyed under cavities filled with cements possessing a high degree of acidity at the time of insertion into the cavity. From a biological point of view it is essential that no irritating drugs be used.

With regard to the question of infection of the pulp: it is very necessary to distinguish between a carious and a traumatic exposure. In cases of carious exposure there will be gross bacterial infection of the pulp and no treatment other than partial or complete removal of the pulp will avail. On the other hand it is inconceivable that the pulp under the lesion described in the first clinical case should not at some period have been subject to irritation through bacterial toxins, and its recovery would lead one to believe that the pulp can tolerate a certain degree of irritation from infective sources. The question of the degree of infection that may be present under a carious lesion can only be assessed clinically at the time of the operation in each individual case.

Our understanding of the changes taking place within the pulp should aid the diagnosis of the condition requiring treatment.

Total...	97.202	37.066	16.986
Determined values (see Table I)	—	37.07	17.22

I think it appropriate here to compare the calculated fluorapatite and CO_2 content of mottled and non-mottled enamel and dentine (Bowes and Murray, 1936). The difference

	Fluorapatite content		CO_2 content	
	Enamel	Dentine	Enamel	Dentine
Mottled (Maldon)	0.85%	1.93%	2.35%	3.8%
Non-mottled (London)	0.665%	0.665%	1.95%	3.18%

in fluorapatite is not so great as the difference in properties might lead one to suppose. It may be pointed out here that mottled enamel and dentine contain significantly more carbonate than non-mottled. However, the value of chemical data is limited in ability to give information about actual molecular structure and arrangement and this leads to a consideration of the ultramicroscopic structure.

The interpretations of the microscopic observations on the structure of enamel present some difficulty and I am not competent to discuss this matter. I would, however, like to consider the ultramicroscopic structure as studied by X-ray—crystallographic analysis. This will summarize the work of Thewlis (1940). We collaborated in a combined chemical and physical investigation of dental enamel and various apatites (Glock, Murray and Thewlis, 1939). X-ray analysis gives information on molecular structure and arrangement and greatly extends the information obtained by chemical analysis. To illustrate this point we may compare diamond and graphite; both are composed of carbon, that is chemically identical, but whereas diamond is one of the hardest substances we know, graphite is used as a lubricant. This difference is due to a difference in arrangement of the carbon atoms in the two substances and it is from X-ray analysis that we know why they are different.

A comparison of X-ray diffraction photographs of enamel with those of some typical apatites led to the same conclusions as made from the results of chemical analyses, namely, that enamel is composed principally of hydroxy-apatite. But of greater interest is the arrangement of these apatite molecules. If molecules in any material are arranged in an orderly manner then the material is crystalline. A random arrangement is present in

amorphous material, such as glass. Few substances are amorphous. Crystals may be of any size, some are microscopic, some ultramicroscopic, the latter are crystallites. Enamel proved to have the molecules of apatite arranged in an orderly manner, but only over ultramicroscopic ranges, that is, enamel is composed of crystallites.

The average size of the crystallites in human enamel is about 0.3μ in diameter. So an enamel prism which is equal to the depth of the enamel and has a breadth of 2 to 5μ must contain multitudes of these crystallites. A point of interest is that these are arranged in the prism according to some plan or pattern, that is they are preferentially orientated. Human enamel shows two plans of preferential orientation, whereas dog's enamel shows only one plan. Different areas of human enamel show different proportions of the two orientations, which will be called the 5 degrees and 40 degrees orientations, referring to the angle the crystallites make with the general direction of the fibre axis. Areas of enamel with regular prisms tend to show double orientation, in fact this predominates in human deciduous enamel. Even along an individual prism there is double orientation. The interprismatic substance also shows crystallites arranged on the plan of double orientation, but whereas the 5 degrees type predominates in the prisms, the other, the 40 degrees type, predominates in the interprismatic substance.

Enamel, both the prismatic and interprismatic substance, gives another test for crystallinity, it is birefringent. Birefringence observations confirm in all respects the X-ray findings, including the difference in crystallite arrangement between the prisms and interprismatic substance.

The study of dentine by the X-ray diffraction method is not so satisfactory, because of the greater proportion of organic matter, but the following facts can be deduced. The main inorganic constituent is again hydroxy-apatite, which exists in crystallites. These are only one-tenth of the size of those of enamel and are as a general rule arranged at random. In some cases preferential orientation was found in translucent zones of primary dentine of the root and in secondary dentine.

It is sometimes difficult to judge from ordinary microscopic study the degree of calcification of enamel in tooth sections, or to compare different areas of enamel or of dentine. For instance, is there really an outer hypercalcified layer to the enamel; are those parts of the enamel, which appear pigmented in ground section, or readily take up stain, of a different degree of calcification from the rest?

Thewlis (1940) made a quantitative micro-radiographic and micro-photometric study of the degree of calcification, as measured from the absorption of soft X-rays, of tooth sections cut and ground to be of even thickness. His investigations showed that "pigmented" enamel and readily stainable enamel are usually less calcified than the rest, that true hypercalcification existed in some teeth at the outer surface of the enamel and that the degree of calcification fell from the outer to the inner side of the enamel. In the dentine there was a similar gradient of falling calcification going from the amelodentinal junction towards the pulp, near the pulp chamber a low degree of calcification, and variable and low calcification in areas with interglobular spaces. Secondary dentine was generally as well calcified as primary.

More recently a new technique, suitable for the examination of the fine detail of hard surfaces, such as those of metals, has been employed by Gerould (1944, 1945) in the U.S.A. for the examination of tooth structure. I refer to the use of the electron microscope. This method of studying structure has advantages over the X-ray and electron diffraction methods in that a visual record on a fluorescent screen or a photographic record of the surface can be obtained.

The resolving power of the electron microscope is more than 100 times that of the best visual microscope, a magnification of 15,000 times is readily possible. Tooth sections cannot be made of the required degree of thinness, which must be less than 1μ , so surface replicas are the objects photographed. These replicas are made by covering the etched surface of the tooth, or etched surfaces of dental structure exposed in sections or by fracturing a tooth, with a plastic material, polystyrene. This makes a negative impression of the surface, which is then reproduced as a positive by depositing on the polystyrene a thin film of silica. This film, which ideally should be of the order of 0.02μ thick, is freed and floated on to a mesh grid. The actual photographs taken of this film are stereoscopic ones and so give detail in depth.

The first problem relating to dental structure investigated by this instrument was a preliminary study comparing the enamel and dentine of fluorosed and non-fluorosed teeth, which showed that the matrix of the fluorosed dentine was of much finer structure. The author (Gerould, 1945) stated that there was no difference in the interprismatic substance of the fluorosed enamel, but the photographs appear to me to show that this material has etched more readily than the non-fluorosed, which I think is possibly due to the generally greater carbonate content of fluorosed teeth.

This method is certainly very suitable for the investigation of hard surfaces and it is to be hoped that some of the electron microscopes in this country may be available for the pursuit of dental research.

Dr. P. Pincus: Dr. Murray has mentioned the organic matter associated with enamel and I wish to bring to notice some further points concerning this organic material.

Earlier estimates of organic material are given as 2%. In 1940 Bird [1] found in 45 teeth, 4.9% organic material in enamel. As against this, Deakins and Volker [2] estimated the organic material as 0.49% to 1.95%, the highest figures being found in carious deciduous teeth and the lowest in carious, young, permanent teeth. Methods of collection and of separation are factors which may affect results. Near the dento-enamel junction, enamel tufts penetrate the enamel.

In 1943 Manly [3] found a structureless, recurrent deposit on human teeth. This adventitious material resembles a keratin and may recur within two weeks of removal. Later, Vallotton [4] divided organic coverings of enamel into two main classes, anatomical and acquired. Nasmyth's membrane, or enamel cuticle, is formed in development and remnants may persist throughout life. Acquired films are largely bacterial in composition, though Manly's film was comparatively free from micro-organisms. On examining enamel pellicle, Vallotton found some similarity to keratin in staining properties, while staining for mucin, amyloid substance and fat were negative. Limited chemical investigation of enamel pellicle failed to give Vallotton any definite indication of its nature though he confirmed Manly's report to the effect that the pellicle consists of a highly insoluble protein.

R. J. Block [5] described keratins in 1939, pointing out that the ectoderm gives rise to the enamel of teeth along with other superficial structures. He differentiates the hardening of squamous epithelium from keratinization, which is the formation of a definite horny structure. According to Block all proteins of ectodermal origin fall into two main groups: eukeratins or true keratins, and pseudo-keratins. Eukeratins resist pepsin and trypsin. Sulphur estimations on 14 keratins of different origin—hair, wool, various skins—gave the lowest sulphur determination at 2.2%, which was the value for snakeskin. When Dr. Schoeller estimated sulphur in enamel protein for me he found sulphur 1.2%.

Dr. Murray and Dr. A. Neuburger suggested testing enamel protein by two methods: (a) To compare the solubility of enamel protein with known keratins in solutions of sodium sulphide, potassium cyanide and sodium thiocacetate (b) to test the action of trypsin and pepsin on such of these proteins as then remained undissolved. The results are shown in Table I, from which it may be seen that enamel protein is a protein of a resistant nature, differing from characteristic keratins [6].

TABLE I.—RESULTS OF TESTS ON KERATINS AND ENAMEL PROTEIN.

(A) Lead acetate test		
Wool, hair, horn, hoof	All +ve	Enamel protein -ve
(B) Sodium nitroprusside test		
Wool, hair, horn, hoof	All +ve	Enamel protein -ve
(C) Solubility and enzymic hydrolysis		
(a) KCN	KCN	KCN
(b) Na ₂ S	Na ₂ S	Na ₂ S
(c) Na thiocacetate	Na thiocacetate	Na thiocacetate
Contact with one of the above for 2 days	Contact with one of the above for 4 days	Contact with one of the above for 4 days followed by trypsin for 24 hrs.
Wool	Dissolves	—
Hair	Dissolves	—
Horn	Resists	—
Hoof	Resists	Dissolves
Enamel protein	Resists	Resists

This last series of tests (C) was carried out at 37°.

(From *The Biochemical Journal* (1939) 33, 694-696.)

Enamel protein is, then, unlike hair, wool, horn and hoof, and yet it cannot be classed as one of the pseudo-keratins of Block and Vickery [7] since it is more and not less

amorphous material, such as glass. Few substances are amorphous. Crystals may be of any size, some are microscopic, some ultramicroscopic, the latter are crystallites. Enamel proved to have the molecules of apatite arranged in an orderly manner, but only over ultramicroscopic ranges, that is, enamel is composed of crystallites.

The average size of the crystallites in human enamel is about 0.3μ in diameter. So an enamel prism which is equal to the depth of the enamel and has a breadth of 2 to 5μ must contain multitudes of these crystallites. A point of interest is that these are arranged in the prism according to some plan or pattern, that is they are preferentially orientated. Human enamel shows two plans of preferential orientation, whereas dog's enamel shows only one plan. Different areas of human enamel show different proportions of the two orientations, which will be called the 5 degrees and 40 degrees orientations, referring to the angle the crystallites make with the general direction of the fibre axis. Areas of enamel with regular prisms tend to show double orientation, in fact this predominates in human deciduous enamel. Even along an individual prism there is double orientation. The interprismatic substance also shows crystallites arranged on the plan of double orientation, but whereas the 5 degrees type predominates in the prisms, the other, the 40 degrees type, predominates in the interprismatic substance.

Enamel, both the prismatic and interprismatic substance, gives another test for crystallinity, it is birefringent. Birefringence observations confirm in all respects the X-ray findings, including the difference in crystallite arrangement between the prisms and interprismatic substance.

The study of dentine by the X-ray diffraction method is not so satisfactory, because of the greater proportion of organic matter, but the following facts can be deduced. The main inorganic constituent is again hydroxy-apatite, which exists in crystallites. These are only one-tenth of the size of those of enamel and are as a general rule arranged at random. In some cases preferential orientation was found in translucent zones of primary dentine of the root and in secondary dentine.

It is sometimes difficult to judge from ordinary microscopic study the degree of calcification of enamel in tooth sections, or to compare different areas of enamel or of dentine. For instance, is there really an outer hypercalcified layer to the enamel; are those parts of the enamel, which appear pigmented in ground section, or readily take up stain, of a different degree of calcification from the rest?

Thewlis (1940) made a quantitative micro-radiographic and micro-photometric study of the degree of calcification, as measured from the absorption of soft X-rays, of tooth sections cut and ground to be of even thickness. His investigations showed that "pigmented" enamel and readily stainable enamel are usually less calcified than the rest, that true hypercalcification existed in some teeth at the outer surface of the enamel and that the degree of calcification fell from the outer to the inner side of the enamel. In the dentine there was a similar gradient of falling calcification going from the amelodentinal junction towards the pulp, near the pulp chamber a low degree of calcification, and variable and low calcification in areas with interglobular spaces. Secondary dentine was generally as well calcified as primary.

More recently a new technique, suitable for the examination of the fine detail of hard surfaces, such as those of metals, has been employed by Gerould (1944, 1945) in the U.S.A. for the examination of tooth structure. I refer to the use of the electron microscope. This method of studying structure has advantages over the X-ray and electron diffraction methods in that a visual record on a fluorescent screen or a photographic record of the surface can be obtained.

The resolving power of the electron microscope is more than 100 times that of the best visual microscope, a magnification of 15,000 times is readily possible. Tooth sections cannot be made of the required degree of thinness, which must be less than 1μ , so surface replicas are the objects photographed. These replicas are made by covering the etched surface of the tooth, or etched surfaces of dental structure exposed in sections or by fracturing a tooth, with a plastic material, polystyrene. This makes a negative impression of the surface, which is then reproduced as a positive by depositing on the polystyrene a thin film of silica. This film, which ideally should be of the order of 0.02μ thick, is freed and floated on to a mesh grid. The actual photographs taken of this film are stereoscopic ones and so give detail in depth.

The first problem relating to dental structure investigated by this instrument was a preliminary study comparing the enamel and dentine of fluorosed and non-fluorosed teeth, which showed that the matrix of the fluorosed dentine was of much finer structure. The author (Gerould, 1945) stated that there was no difference in the interprismatic substance of the fluorosed enamel, but the photographs appear to me to show that this material has etched more readily than the non-fluorosed, which I think is possibly due to the generally greater carbonate content of fluorosed teeth.

recording that loss of calcium salts from enamel, apart from acid attack, appears possible. One may here mention Grossman [23] who estimated hydrogen-ion concentration found in carious dentine by electrometric methods; using 57 teeth, he found an average pH value of 6.51.

On the clinical side there is the work of Brucker [24] who examined over 11,000 first molars and concluded that failure of cusps to coalesce is not a factor in caries. From an examination of 6,000 children, Klein and Palmer [25] found that lower first and second molars are the teeth most susceptible to caries. Klein [26] next treated teeth of 474 children with ammoniacal silver nitrate, which he reduced with eugenol, treatment being spread over a three-month period, some teeth in each mouth being left untreated to serve as controls. Fresh attacks of caries occurred, and spread of the original carious condition extended to about the same degree in both treated and control teeth. He concluded that this treatment "does not to any significant degree prevent or arrest caries in this highly susceptible tooth".

It would therefore appear that the organic material associated with enamel is a factor in caries. This organic material is a protein of a nature resistant to enzyme and to chemical action; it also resists bacterial attack. Bacteria of course act through the enzymes they form, and such enzymes—proteinases—are often associated with a low oxygen tension such as exists in saliva [27]. Oxidation-reduction (or redox) potentials are outside the scope of this paper, as is their relation to hydrogen-ion concentration. However, addition of saliva will change methylene-blue from the oxidized (blue) state to the reduced (colourless) state. Further, material gathered from the inner surface of cheeks, lips, from between natural teeth, in fact from practically any mouth surface, will on culture give a strict obligate anaerobe, *micrococcus gazogenes*, described by Weinberg [28] as "Anaërobie strict".

From these observations it follows that a low oxygen tension exists in saliva. This condition of low oxygen tension affects determination of hydrogen-ion values as pointed out by Stephan [29]. Both Wessinger [30] and Eisenbrandt [31] attempted to correlate pH values with redox potentials; in the estimation of the latter of these, they met difficulties. Wessinger adds that deviation in pH value as estimated by quinhidrone will probably be greater the farther the redox potential is removed from zero; this lowering exists in saliva.

Further work on saliva showed in my experiments that a pyruvic dehydrogenase and an oxidase are both present in saliva, though I found it impossible to exclude bacterial growth as a possible factor in the production of these enzymes. The collection of sterile human saliva was not found possible.

Though enamel protein resists bacterial attack, attack by certain bacteria from carious material is possible. Such proteolytic bacteria may, *in vitro*, produce lesions of enamel. Lastly, saliva has been found to show reducing power, that is, conditions in the mouth may be favourable to growth of anaerobes amongst which are found bacteria capable of causing proteolysis.

Acknowledgments.—The experimental work referred to was supported by a grant from the Medical Research Council; clinical material and laboratory facilities were made available by the Royal Dental Hospital.

resistant to enzymic digestion than the true keratins. It appears to be much more resistant than human skin.

From enamel protein may I turn to matters more nearly clinical and possibly more directly concerned with caries. In 1939, following experiments by Dr. Fish [8] with dogs, I carried out experiments on sound teeth in the human mouth, teeth condemned to removal for orthodontic reasons. A cap containing methylene-blue was cemented on to the tooth. It was found that enamel stained blue in about a month and that in parts the penetration approached the dentine. It was my opinion at the time that longer exposure to the dye might have resulted in penetration to the dentine. In 1943 Berggren [9] did in fact find that methylene-blue placed in caps cemented on to human teeth in the mouth may penetrate sound enamel to the dentine. This penetration of sound enamel has been confirmed by work with radio-active substances in animals by Volker and Sognnaes [10].

From these references to enamel protein as to nature and permeability, I pass to caries. As far back as 1907 Preiswerk [11, 12] stated that caries might occur in alkaline conditions, organic ground substances being first destroyed—a disintegration brought about by proteolytic action, the calcium salts then falling out. It is possible, he stated, that caries may be produced in two ways at least (a) by acids dissolving inorganic matter and subsequent splitting-up of organic matter by proteolytic organisms, and (b) by destruction of the organic matter and as a result the setting free of the inorganic matter which then falls away.

In 1938 I attempted to separate in pure culture, bacteria which could attack enamel protein. Though pure cultures were not obtained, the cultures were narrowed down to a very small number of types. Despite this lack of success, I exposed sound teeth to cultures of known proteolytic properties and found that sound enamel was attacked in some instances [13].

(Here the speaker showed slides illustrating lesions of enamel reproduced from the *British Dental Journal*, November 1937.)

These lesions of enamel followed attack by bacteria, an attack in which acid played no part [14]. Estimations of hydrogen-ion concentration showed that the cultures remained either neutral or slightly alkaline, between pH 7 and 8. It is thought that the production of these lesions provides some evidence of the possibility of breakdown of enamel in an alkaline medium, by the attack of proteolytic bacteria. The bacteria used in these experiments were separated from carious material by routine methods.

In 1939, Gins [15] described experiments in which sound and slightly carious teeth were exposed to bacteria for periods up to fifteen months. In some cases he found further caries, which he attributed to the action of anaerobic bacteria. It was an unusual method—he placed extracted teeth in moist, sterile sea-sand, and observed, without surprise one gathers, that “normal mouth flora disappeared after three to four months”. In Gins’ opinion, saprophytic anaerobes may become pathogenic and so cause caries.

This concept of attack on enamel protein has been elaborated by Hinds [16] and by Gottlieb [17]. Hinds studied enamel in hard-ground sections and by experiments with penetration by silver nitrate. He came to the conclusion that “caries of enamel is defined as invasion of organic matter of enamel by proteolytic organisms” and that teeth differ in their resistance to penetration by silver nitrate. Gottlieb connected up proteolysis and caries, relying on microscopic examination of hard-ground and microtome preparations. Applebaum also [18] described tissue changes in enamel caries, including a translucent zone which is not decalcified.

In addition to the cases of enamel absorption previously described [14], Glickman and Bibby [19] describe a case of absorption of a buried human canine. In their photomicrographs, connective tissue is seen occupying space presumably formerly occupied by enamel, assuming enamel was present originally as it was elsewhere on the crown of this tooth.

It is obvious that absorption of dental enamel and of dentine or bone, differ inasmuch as enamel contains far less organic material.

Keeping this difference in mind, one may glance at another field of study. Brash [20] stated that “the fundamental problem of the developmental mechanics of bone is . . . the control of absorption and not of accretion of bone”. Loyatt Evans [21] quoting Brash, adds: “This general conclusion, however qualified, is inescapable. It raises reabsorption to a position of great importance and significance.” In 1943 McLean [22] pointed out “it thus appears that the decalcification of bone is a misnomer, and that the concept of the destruction of bone by resorption, involving simultaneous dissolution of both its organic and its inorganic constituents must be substituted for that of decalcification”.

By experiment I have shown that enamel *in vitro* may be lost without decalcification, and while it would be unwise to follow the comparison about bone too far, it is worth

A Case of Kostecka's Operation for the Correction of the Prognathous Mandible

By C. BOWDLER HENRY, L.D.S.Eng., M.R.C.S., L.R.C.P.

In the whole of orthodontics there is probably no deformity so resistant to treatment, even when the child is seen early, as the elongating mandible. In this communication I am not concerned to discuss the aetiology nor the orthodontic procedures which may be tried in children to overcome it. My communication is solely to exhibit an adult patient, while still under post-operative fixation, as an example of the operation devised by Professor F. Kostecka, M.D., of Prague. Various operations have been tried, ranging from the removal of a segment of bone on each side of the mandibular corpus to sectioning the rami—Babcock, v. Eiselsberg, Limberg, Kostecka—but for simplicity, speed and lack of shock, with an adequate margin of safety from injuring important structures, no variety has appealed to me so much as Kostecka's, whose ciné-film I had seen at the Eighth International Dental Congress.

It is for these reasons that I have ventured to show the case while under treatment, instead of when finished, so the details of operation, method of splinting, pre- and post-operative radiographs may be more usefully criticized.

The patient, M. K., aged 29, was seen by Mr. H. W. Kander, L.D.S.R.C.S.Edin., Acting Dental Surgeon to the Friends' Ambulance Unit, who referred him to me on September 17, 1945, when models and photographs were taken and the operation planned. Unfortunately, owing to difficulties of in-patient accommodation, it was not possible to operate until February 25, 1946, but the delay, irritating at the time, resulted in my being able to re-establish communication with Professor Kostecka through the good offices of his former pupil—and my recent colleague—Major C. König, M.D. Prague, Chief Dental Surgeon of the Czechoslovak Armed Forces.

Professor Kostecka most generously sent me his particular mounted needle and Gigli saws and, moreover, Major König, having returned from a recent visit to Professor Kostecka's Clinic, kindly attended my operation and gave me valuable assistance and advice, which I am very pleased to acknowledge in this communication.

Pre-operative photographs, stereoscopic radiographs (Drs. Coldwell and Allchin) and dental study models were prepared. Fig. 1 shows the upper and lower models mounted on a bite-slab in the position of the patient's natural articulation. After examining these with the radiographs, I came to the conclusion that the best aesthetic result would be obtained when the chin had been translated backwards sufficiently to bring the teeth into normal occlusion. The models were therefore re-articulated empirically so as to give, as far as possible, a "normal" bite (fig. 2).

FIG. 1.

FIG. 2.

A cast metal inter-dental cap splint was then constructed for each jaw separately and a rod and tube device for locking the two members together was arranged on each side so that the splint could only be locked up when the jaw had been pushed backwards to precisely this pre-determined position of the upper and lower teeth.

On the day before operation, the upper and lower members of the splint were separated and cemented respectively on the teeth.

The operation was throughout conducted under regional novocain (2%) with omnipon and scopolamine premedication.

Both sides having been anesthetized by mandibular block and subcutaneous infiltration, Kostecka's needle was passed behind the posterior border of the left ramus and was made to emerge through the cheek close to the angle made by the anterior border of the ramus and the inferior edge of the zygomatic arch. The Gigli wire saw was attached and drawn back through the wound. With very few strokes the ramus was bisected. The right condyle was similarly sectioned (figs. 3, 4 and 5).

There was no difficulty in pushing the jaw back and immediately locking the splints in the predetermined position by passing the rods through the interdigitating tubes.

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 6.

Fig. 6 of the patient on the operating table before bandaging shows the insignificant wounds.

FIG. 7.

FIG. 8.

As a prophylactic I used penicillin parenterally—100,000 units daily for three days with an extra 100,000 units during operation. This was probably not necessary but I deemed it a wise precaution. Healing was uneventful.

The patient suffered some pain on swallowing for the first three days but this passed off. Trauma was minimal and neither anodynes nor re-dressings of the punctures were found to be necessary.

As will be seen from the post-operative radiographs (figs. 7 and 8), the osteotomy is made beneath the sigmoid notch and as high as possible above the mandibular foramen, thus avoiding the inferior dental vessels and nerve. In this case the operative displacement necessary to correct the profile in so gross an abnormality was, as the radiographs show, one-half of the anteroposterior width of the rami, and the anteroposterior view shows separation of the fragments on each side (fig. 8).

Figs. 9 to 11 show the case before operation and figs. 12 to 14 are photographs taken sixteen weeks after operation, at which time the mandible was functioning normally, there being neither trismus nor weakness of bite. He had been eating ordinary food for the previous eight weeks.

FIG. 9.

FIG. 10.

FIG. 11.

FIG. 12.

FIG. 13.

FIG. 14.

The further progress and the strength of the mandibular function will be watched with interest and radiographs may be shown at a later meeting.

Kostecka advocates splinting for twelve weeks. The advantages of the rod and tube device for locking the inferior member of the splint to the superior one is that, while being rigid when locked, it nevertheless allows the patient, when controlled movement is permitted, easily to withdraw the rods for meals and to reinsert them again without having to fiddle with screws.

POSTSCRIPT (30.8.46).—This patient was seen to-day. He had complete mandibular function with a strong masticatory bite and no limitation of opening.—C. B. H.

Professor R. V. Bradlaw read a communication on Oral Pathology. This was well illustrated by a large number of coloured lantern slides.

MEETING HELD AT THE MEDICAL SOCIETY OF LONDON, 11, CHANDOS STREET,
LONDON, W.1.

Homologous Serum Jaundice

By W. H. BRADLEY, D.M.

Senior Medical Officer, Ministry of Health

In May 1937 the two children of a well-to-do family living near Oxford died on consecutive days of acute yellow atrophy of the liver. Four days before death one child, a girl aged 7, vomited after breakfast but was able to travel with her mother to London and back by train. She vomited again after returning home, and was restless during the night. On the second day she was at first sleepy but later irritable: the restlessness became marked and she complained of some abdominal pain. Her doctor, a careful man, found no signs of physical disease and the mother chastised the child for screaming and behaving irrationally. Next day the condition changed dramatically, the child vomited altered blood, became uncontrollable and for the first time was noticed to be slightly jaundiced. She died twenty-four hours later after a period of coma with marked neurological signs.

The 4½-year-old brother's illness began a day after his sister's and ran an almost identical course. Their nurse also developed jaundice but survived.

Measles serum jaundice.—During an inquiry by Medical Officers to the Ministry of Health, it became known that, within a month, two other young children in Oxford had died of hepatic necrosis after similar illnesses and that all four and the nurse had received injections of a single batch of measles convalescent serum nine or ten weeks previously. Eventually 109 recipients of this batch of serum were traced; 41 scattered over nine widely separated areas in England subsequently became ill, 37 of them with jaundice, and 8 died of hepatic necrosis: a phenomenally high fatality rate of 12%. More significantly they all died between the 61st and 93rd day after receiving serum (MacNalty, 1937; Probert, 1938). Subsequently, and particularly as the result of inquiries made by the Medical Officer of Health for Leeds (Jervis, 1940), a few other batches of

measles serum were suspected of being icterogenic, one with fatal results, but the overall incidence amongst the thousands of persons who had received measles serum was so low that nothing was done to discourage its use. Nevertheless, the distributors of the implicated batches discontinued the preparation.

Yellow fever vaccine jaundice.—A similar sequence of events, following the administration of yellow fever vaccine, was reported by Findlay and MacCallum (1937, 1938) who, in the course of five years, had vaccinated 3,100 persons, 89 of whom developed jaundice two to seven months later. Findlay, MacCallum and Murgatroyd (1939) were satisfied that this hepatitis was not due to the yellow fever virus itself but suspected contamination with an icterogenic agent during tissue culture involving the use of human serum. They changed the strain of seed virus and observed no further cases of jaundice following the next 8,000 vaccinations (Findlay, 1940).

Jaundice with mad staggers in horses.—Both clinically and circumstantially there appeared to be a close analogy between these incidents and jaundice with mad staggers which had, on four occasions, been reported in large herds of horses during the course of immunization with various antigens administered in horse serum (Theiler, 1919; Gordon, 1935; Marsh, 1937; Stagsvold, 1938) and because of this similarity the condition was called *homologous serum jaundice*, a hepatitis characterized by a long incubation period of from two to four months following the administration of blood from the same species. Extensive investigations (1943, Medical Officers to Ministry of Health) were inconclusive but the records of these investigations were of considerable value when, in May 1942, hundreds of U.S. soldiers in transit by ship to the British Isles became jaundiced and the question arose whether they were suffering from a communicable disease and whether the convoys affected should be quarantined.

*"Post-vaccinal jaundice."*¹—It was known that during mobilization of the American Army, after the Japanese raid on Pearl Harbour on December 7, 1941, all troops received injections of yellow fever vaccine containing human serum, and in England the tentative conclusion that the men with icterus were suffering from homologous serum jaundice was reached without difficulty. Previous experience had suggested that the condition was rarely, if ever, communicable by natural routes and troop movements were allowed to proceed without restriction. These conclusions were speedily confirmed as the result of the surveys by Colonel J. E. Gordon (U.S.M.C.) in North Ireland which showed that icterogenicity was confined to certain batches of vaccine with adjacent serial numbers, strong evidence that the factor common in the implicated batches was not the tissue culture but the human serum used as a vehicle for the vaccine.

Meanwhile, in America, where the outbreak of yellow fever vaccine jaundice was first noticed in March 1942, Dr. Sawyer's team (1944) immediately began investigations amongst the U.S. troops in California, Hawaiian Islands and Oregon. The team had information concerning an earlier outbreak of yellow fever vaccine jaundice in Brazil (Fox *et al.*, 1942) where the evidence against serum used in the preparation of the vaccine was not at all convincing. However, Sawyer's studies conclusively exonerated the yellow fever virus itself for the same seed contributed to all the American vaccine while icterogenicity appeared to be associated with a few only of the lots used. In fact 9 of 117 lots investigated were responsible for 23,664 cases, an overall incidence of 56.64 per thousand doses of vaccine. On the other hand, 70 lots representing 54.4% of the entire amount of vaccine supplied to the U.S. Army during the period were associated with a jaundice attack rate of only 0.41 per 1,000 doses, a figure falling within the normal expectations of jaundice from natural causes. By chance the U.S. Navy escaped with 691 cases of jaundice associated with 1,645,740 doses of vaccine: an incidence of 1.4 per 1,000; again within normal expectation of jaundice from natural causes. The vaccine supplied to both Army and Navy came from the same source and this strange discrimination was, at first, puzzling, until it was discovered that the Navy had been supplied with a small part of one highly icterogenic batch only. With this batch 271 persons were injected and 31 developed jaundice.

This, the luck of the U.S. Navy, should be remembered for it is typical of the vagaries of incidence, resulting from accidents of distribution, which have added to the difficulties of investigating homologous serum jaundice. In consequence most of the illuminating experiences have arisen fortuitously and not as the result of organized study. One such experience played a considerable part at the time the problem of yellow fever vaccine jaundice arose in American troops approaching the British Isles.

¹ "Post vaccinal jaundice" is the term employed in American literature when referring to yellow fever vaccine jaundice.

Mumps serum jaundice.—The American Red Cross,—Harvard Field Unit at Salisbury, attempted serum prophylaxis against a mumps outbreak in a unit of the British Tank Corps stationed in Dorset. Two batches of pooled serum each from 11 volunteers recently convalescent from mumps were given to 266 and subsequently to 204 of the same men at 14-day intervals. 226 men were followed up. 44.7% developed hepatitis, 44 to 123 days later (Beeson *et al.*, 1944).

Pappataci vaccine jaundice.—A similar experience occurred in Southern Russia in 1939 but did not come to notice in England until after the events already described. In 1937 Sergiev *et al.* (1940) gave injections of active pappataci virus and convalescent serum to 500 persons in a sandfly-fever area on the Black Sea coast. These injections were innocuous. In 1939 a similar trial was made using 0.01 ml. of serum containing virus suspended in unstated quantities of serum from sandfly-fever convalescents. 92 of 350 persons who received this treatment developed jaundice within five months, the majority between the 85th and 95th day after injection. In this instance some of the pappataci virus-containing serum obtained from a patient at the onset of sandfly fever was tested by deliberate injection into four persons, one of whom developed jaundice four months later. If this single experimental case can be taken as proving that the "virus serum" was icterogenic then the main outbreak had resulted from injections of no more than 0.01 ml. of serum.

Post-transfusion hepatitis.—When these several instances (measles and mumps convalescent serum, yellow fever and pappataci vaccines) were considered together it became abundantly clear that human serum had been the vehicle of hepatotoxic agents and at the Ministry of Health it seemed inevitable that transfusions of whole blood or serum would, sooner or later, be found to result in homologous serum jaundice. However, one suggestive case only had come to the Ministry's notice: in 1941, a man with a perforated duodenal ulcer received seven bottles of whole blood and one of plasma in July at Chelmsford and developed profound cholæmia seven weeks later at Wolverhampton; but on the strength of this case a meeting of Civilian and Military Transfusion Officers and other interested persons was called at the Ministry on August 13, 1942. By a surprising coincidence the first intimation of any appreciable trouble following transfusion had been received by one of the Transfusion Officers on the preceding day. This occurred in a group of 50 patients given massive transfusions of serum and plasma by way of treatment for peripheral vascular disease. During these investigations, Morgan and Williamson (1943) traced 15 of these patients and found that 9 had become jaundiced from 49 to 107 days after the last transfusion. In five the illness was severe and protracted.

During 1943 several other observers reported cases of jaundice during the second, third and fourth months after transfusion. Some of these cases died of hepatic necrosis and in view of the comparative rarity of acute yellow atrophy of the liver, even at a time when epidemic hepatitis was prevalent, these few deaths in persons previously transfused were thought to have a significance but it was impossible to prove any direct association with the preceding transfusion. However, autopsy and biopsy material from some of these cases was compared with that from measles serum, mumps serum and yellow fever vaccine jaundice, and with N.A.B. jaundice and epidemic hepatitis, by Dible, McMichael *et al.* (1943), who concluded: "Although there may be different ætiological factors in each of the above groups, we have not found any recognizable histological criteria for their differentiation." Differentiation by other laboratory methods proved equally unhelpful and the identification, for the purposes of study, of cases of post-transfusion jaundice had to depend upon the weight of circumstances or some unusual chance such as that which brought "Batch 034" to notice (Bradley, Loutit, Maunsell (1944)). This batch of dried transfusion serum was prepared specially by the M.R.C. Transfusion Reaction Sub-Committee for the purpose of observing the immediate reactions of allergic and normal subjects to skin test doses and subsequent transfusion. Fortunately, some of the recipients remained for several weeks under observation for their allergic condition and were noticed to become jaundiced at about the same time. Follow-up showed that 57% of 75 recipients became jaundiced 45 to 104 days after injection. The incidence of jaundice was no greater in the allergic than in the normal controls. The dose had varied from 0.1 ml. intracutaneously to as much as 1,200 ml. intravenously but there appeared to be no correlation between dosage or route and virulence or icterogenicity.

The hepatitis produced by batch 034 was uniformly mild, a feature which encouraged MacCallum and Bradley (1944) to use it deliberately in the induction of jaundice in intractable cases of rheumatoid arthritis. Our intentions were benign and our objectives two in number: first, to learn something about hepatitis and, secondly, to see whether

measles serum were suspected of being icterogenic, one with fatal results, but the overall incidence amongst the thousands of persons who had received measles serum was so low that nothing was done to discourage its use. Nevertheless, the distributors of the implicated batches discontinued the preparation.

Yellow fever vaccine jaundice.—A similar sequence of events, following the administration of yellow fever vaccine, was reported by Findlay and MacCallum (1937, 1938) who, in the course of five years, had vaccinated 3,100 persons, 89 of whom developed jaundice two to seven months later. Findlay, MacCallum and Murgatroyd (1939) were satisfied that this hepatitis was not due to the yellow fever virus itself but suspected contamination with an icterogenic agent during tissue culture involving the use of human serum. They changed the strain of seed virus and observed no further cases of jaundice following the next 8,000 vaccinations (Findlay, 1940).

Jaundice with mad staggers in horses.—Both clinically and circumstantially there appeared to be a close analogy between these incidents and jaundice with mad staggers which had, on four occasions, been reported in large herds of horses during the course of immunization with various antigens administered in horse serum (Theiler, 1919; Gordon, 1935; Marsh, 1937; Stagsvold, 1938) and because of this similarity the condition was called *homologous serum jaundice*, a hepatitis characterized by a long incubation period of from two to four months following the administration of blood from the same species. Extensive investigations (1943, Medical Officers to Ministry of Health) were inconclusive but the records of these investigations were to prove of considerable value when, in May 1942, hundreds of U.S. soldiers in transit by ship to the British Isles became jaundiced and the question arose whether they were suffering from a communicable disease and whether the convoys affected should be quarantined.

"Post-vaccinal jaundice."¹—It was known that during mobilization of the American Army, after the Japanese raid on Pearl Harbour on December 7, 1941, all troops received injections of yellow fever vaccine containing human serum, and in England the tentative conclusion that the men with icterus were suffering from homologous serum jaundice was reached without difficulty. Previous experience had suggested that the condition was rarely, if ever, communicable by natural routes and troop movements were allowed to proceed without restriction. These conclusions were speedily confirmed as the result of the surveys by Colonel J. E. Gordon (U.S.M.C.) in North Ireland which showed that icterogenicity was confined to certain batches of vaccine with adjacent serial numbers, strong evidence that the factor common in the implicated batches was not the tissue culture but the human serum used as a vehicle for the vaccine.

Meanwhile, in America, where the outbreak of yellow fever vaccine jaundice was first noticed in March 1942, Dr. Sawyer's team (1944) immediately began investigations amongst the U.S. troops in California, Hawaiian Islands and Oregon. The team had information concerning an earlier outbreak of yellow fever vaccine jaundice in Brazil (Fox *et al.*, 1942) where the evidence against serum used in the preparation of the vaccine was not at all convincing. However, Sawyer's studies conclusively exonerated the yellow fever virus itself for the same seed contributed to all the American vaccine while icterogenicity appeared to be associated with a few only of the lots used. In fact 9 of 117 lots investigated were responsible for 23,664 cases, an overall incidence of 56.64 per thousand doses of vaccine. On the other hand, 70 lots representing 54.4% of the entire amount of vaccine supplied to the U.S. Army during the period were associated with a jaundice attack rate of only 0.41 per 1,000 doses, a figure falling within the normal expectations of jaundice from natural causes. By chance the U.S. Navy escaped with 691 cases of jaundice associated with 1,645,740 doses of vaccine: an incidence of 1.4 per 1,000; again within normal expectation of jaundice from natural causes. The vaccine supplied to both Army and Navy came from the same source and this strange discrimination was, at first, puzzling, until it was discovered that the Navy had been supplied with a small part of one highly icterogenic batch only. With this batch 271 persons were injected and 31 developed jaundice.

This, the luck of the U.S. Navy, should be remembered for it is typical of the vagaries of incidence, resulting from accidents of distribution, which have added to the difficulties of investigating homologous serum jaundice. In consequence most of the illuminating experiences have arisen fortuitously and not as the result of organized study. One such experience played a considerable part at the time the problem of yellow fever vaccine jaundice arose in American troops approaching the British Isles.

¹ "Post vaccinal jaundice" is the term employed in American literature when referring to yellow fever vaccine jaundice.

fluid was necessarily the vehicle since some of the patients received in addition to transfusion, other parenteral therapies, for example intravenous anæsthetics or penicillin. Unless the hospital records have been grossly misleading it would appear that whole blood has been responsible for hepatitis more frequently than was at first expected. 115 histories state the nature of the blood product transfused. 24 patients received whole blood only, 20 serum or plasma only, and the remaining 71 both whole blood and a product. The experience of the Emergency Medical Service is not unique for at one time in 1945 acute massive necrosis of the liver following transfusion was the major cause of death in U.S. hospitals in the United Kingdom, accidents and pneumonia excepted.

Histology.—I was able to see the case histories and sections from 21 American soldiers dead from this cause. Coma preceded death in all cases; encephalitis was diagnosed in some and jaundice was first noticed after death in 2. The wounds for which the men were transfused were severe in half the cases only, and the patient's condition at the time of onset of hepatitis was fair or good in the majority. The histological appearances suggested that the hepatic necrosis in these fatal cases was sudden and complete and probably preceded or coincided with the onset of symptoms. The biliary passages were patent and healthy, but, unfortunately, there was no statement concerning the presence of bile in the alimentary tract. The livers of those who died before, or within a day or two, of the appearance of jaundice were virtually destroyed, yet showed minimal cellular reaction and no signs of regeneration. Phagocytic infiltration and regeneration of liver columns became more apparent as the interval between jaundice and death increased.

Treatment.—This observation, which is in line with chemical findings, has, I believe, a bearing on treatment, the rationale of which should be to support all the functions, particularly the protein function of the liver until regeneration is well advanced and to reduce energy consumption to a minimum until a weight gain is well established. Dr. Magee will comment on a hopeful line of treatment which has resulted in the only recoveries from coma I have encountered in my series of post-transfusion hepatitis.

Latent period.—Chart I, which includes under "casual" 12 deaths which have been brought to my notice, not as a result of survey, but casually by a Transfusion Officer and others, shows how characteristic is the long interval of two to four months.

Diagnosis.—When the normal expectation of hepatitis from other causes is considered in relation to the figures given for the incidence of jaundice following transfusion (see

CHART I.—Duration of latent period (days) from transfusion to jaundice.

Table) the following statement appears to be justified: "When hepatitis occurs 40 to 120 days after the administration of a human blood product, or other parenteral therapy, it is almost certainly homologous serum jaundice and must be treated as a disease with an appreciable mortality."

Communicability.—MacCallum (1946) in the paper which follows this will deal with experimental transmissions, but the question still remains whether homologous serum jaundice is ever communicated naturally. I believe it is occasionally, and after a long incubation period. In a previous paper (Min. Health, 1945) an outbreak in a "gold"

Hench's (1938) claim that spontaneous jaundice gave rheumatoids a holiday from their pain was true. While I have little doubt that hepatitis, in some way, interrupts the course of rheumatoid arthritis, I feel strongly that until we understand homologous serum jaundice better it can be used as a therapeutic agent only for research purposes. However, by these experiments on rheumatoids it was proved beyond doubt that the icterogenic agent was resident in the serum and that yellow fever vaccine jaundice and batch 034 jaundice had not resulted from a natural spread of disease or from accidental syringe transmission. For by now we were beginning to suspect that outbreaks of jaundice in arspenamine, chrysotherapy and other clinics were merely examples of homologous serum jaundice, the icterogenic agent being communicated through imperfectly sterilized syringes (Min. Health, 1945).

The relative benignity of batch 034 and the regularity with which, even after two years of storage, it continued to produce jaundice in about 50% of the volunteers to which it was administered in subsequent trials, were in marked contrast to the virulence and inconsistency of another batch—045—which came under special observation. This batch was brought into use in the "allergic" trials when batch 034 was withdrawn because it had produced jaundice. It first had appeared to be innocuous until two women who had received it and other blood products intravenously died of acute yellow atrophy 97 and 105 days after transfusion. As far as could be ascertained jaundice did not occur in any other recipients of this batch of serum.

By now the Medical Research Council Transfusion Committee had begun to take part in the investigations and the transfusion officers to work out and apply measures calculated to give some control. I will not discuss these measures, which are not particularly hopeful, but will try to give you some idea of the magnitude of the problem.

The E.M.S. statistical office has searched the records of every fifth admission to E.M.S. hospitals for mention of jaundice and transfusion with the following provisional results which have been provided by Dr. Percy Stocks and Miss E. M. Brooke.

JAUNDICE INCIDENCE AFTER BLOOD TRANSFUSION.

Provisional figures obtained up to February 28, 1946, in the course of a search by the Ministry of Health's Statistical Branch at Norcross of E.M.S. Hospital records of 1940-1945 in-patients.

Group whose hospital records were examined	Total patients whose records have been examined to date	Number in whom jaundice developed during observation	Number of those who died subsequently to jaundice	Incidence rate in observation period (and standard error)
Service patients under observation 3 months or more after transfusion or injury (or who developed jaundice within that period)—				
(a) Injured patients who were transfused ...	1,316	124	17	94±8
(b) Sick patients who were transfused ...	82	16	7	(195)
(c) Injured patients who were not transfused	6,350	6	0	9±3
All males in Services aged under 35 in the United Kingdom in 1942-43	About 63,000 coded for all diseases and injuries	About 1,050 admitted with jaundice and no history of transfusion	Not ascertained	About 2 per 1,000 in 3 months

Analysis of jaundice cases in groups (a) and (c) of above table, according to theatre of war in which injury occurred.

	(a) Transfused			(b) Not transfused		
	Total examined	Jaundice developed	Died after jaundice	Total examined	Jaundice developed	Died after jaundice
Theatre of war						
Mediterranean	308	55	6	905	0	0
Western Europe	613	55	9	2,133	0	0
Far East	30	5	1	80	0	0
United Kingdom	107	8	1	1,240	3	0
Not stated	258	1	0	1,992	3	0
Total	1,316	124	17	6,350	6	0

These figures require correction because other causes may have produced jaundice. I have, therefore, scrutinized the histories of 140 cases of jaundice in transfused persons and believe that homologous serum jaundice was the most probable diagnosis in 82 per 1,000 transfused persons with a case fatality of 12%. There is, undoubtedly, a *tertium quid* somewhere in this high fatality and obviously it cannot be concluded that transfusion

fluid was necessarily the vehicle since some of the patients received in addition to transfusion, other parenteral therapies, for example intravenous anaesthetics or penicillin. Unless the hospital records have been grossly misleading it would appear that whole blood has been responsible for hepatitis more frequently than was at first expected. 115 histories state the nature of the blood product transfused. 24 patients received whole blood only, 20 serum or plasma only, and the remaining 71 both whole blood and a product. The experience of the Emergency Medical Service is not unique for at one time in 1945 acute massive necrosis of the liver following transfusion was the major cause of death in U.S. hospitals in the United Kingdom, accidents and pneumonia excepted.

Histology.—I was able to see the case histories and sections from 21 American soldiers dead from this cause. The histological appearances suggested that the hepatic necrosis in these fatal cases was sudden and complete and probably preceded or coincided with the onset of symptoms. The biliary passages were patent and healthy, but, unfortunately, there was no statement concerning the presence of bile in the alimentary tract. The livers of those who died before, or within a day or two, of the appearance of jaundice were virtually destroyed, yet showed minimal cellular reaction and no signs of regeneration. Phagocytic infiltration and regeneration of liver columns became more apparent as the interval between jaundice and death increased.

Treatment.—This observation, which is in line with chemical findings, has, I believe, a bearing on treatment, the rationale of which should be to support all the functions, particularly the protein function of the liver until regeneration is well advanced and to reduce energy consumption to a minimum until a weight gain is well established. Dr. Magee will comment on a hopeful line of treatment which has resulted in the only recoveries from coma I have encountered in my series of post-transfusion hepatitis.

Latent period.—Chart I, which includes under "casual" 12 deaths which have been brought to my notice, not as a result of survey, but casually by a Transfusion Officer and others, shows how characteristic is the long interval of two to four months.

Diagnosis.—When the normal expectation of hepatitis from other causes is considered in relation to the figures given for the incidence of jaundice following transfusion (see

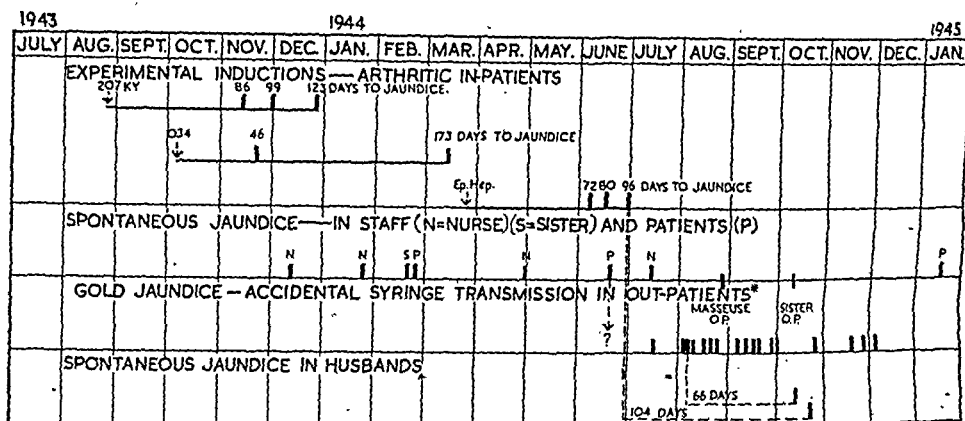

CHART I.—Duration of latent period (days) from transfusion to jaundice.

Table) the following statement appears to be justified: "When hepatitis occurs 40 to 120 days after the administration of a human blood product, or other parenteral therapy, it is almost certainly homologous serum jaundice and must be treated as a disease with an appreciable mortality."

Communicability.—MacCallum (1946) in the paper which follows this will deal with experimental transmissions, but the question still remains whether homologous serum jaundice is ever communicated naturally. I believe it is occasionally, and after a long incubation period. In a previous paper (Min. Health, 1945) an outbreak in a "gold"

clinic is described. Chart II shows the chronology of these events, and indicates the occurrence of jaundice in the husbands of two women with jaundice after intervals of 66 and 104 days.

207 KY = 2.0 c.c. subcutaneously of Batch 207 KY serum given to 10 volunteers.

034 = 50 c.c. intravenously of Batch 034 serum given to 4 patients (*vide* Bradley, Loutit and Maunsell, 1944).

EP.Hep. = 1.25 c.c. subcutaneously of serum from case of epidemic hepatitis given to 6 volunteers.

*Not more than 40 individuals at risk.

CHART II.—Dates of onset of jaundice at a rheumatism clinic.

CONCLUSION

Post-transfusion jaundice has been of considerable importance during the war. It is an unnatural hazard and doubly tragic because of this and the way in which it has so frequently brought the surgeon's efforts to naught. The need for a method of preventing it without withholding transfusion is great. Furthermore, so long as the hazard of homologous serum jaundice exists we shall hesitate to apply extensively serum or immune globulin prophylaxis in measles, mumps, epidemic hepatitis, influenza and other virus diseases which may be amenable to attenuation or prevention by this method.

Lastly, and perhaps most important, this experience with homologous serum jaundice has shown that small quantities of blood, conveyed during therapy from person to person in a variety of ways, can incidentally carry disease. Whereas jaundice is a striking clinical sign and hepatitis easily diagnosed, less spectacular infections might, on occasion, be passed round by the same means without the accidental nature of the transmission being recognized. Parenteral and blood therapies have provided us with great advantages, but we must keep a watch on them in order to detect and eliminate, as soon as possible, any undesirable features tending to vitiate or discredit them.

Homologous Serum Hepatitis

By F. O. MACCALLUM, M.D., B.Sc.

IN 1937 MacNalty reported the first obvious cases of homologous serum hepatitis in Great Britain. The disease occurred in individuals who had been injected with pooled serum from measles convalescents or pooled serum from supposedly normal adults. At the same time Findlay and MacCallum described cases of hepatitis, probably of similar origin, in individuals who had been injected with yellow fever vaccine containing human serum. Further incidents of a similar nature occurred in Brazil, Great Britain and U.S.A. As a result of the use of blood products on a massive scale during the period 1939-1945, a sufficient number of different "outbreaks" of homologous serum hepatitis occurred to make the condition recognized as a definite entity. Because the disease could not be transmitted to laboratory animals experimental studies have been carried out in man. The information obtained by inoculation of known icterogenic sera of this type was summarized by MacCallum in 1944. Since then numerous reports of experimental work on this disease have appeared. The relevant data, old and new, which bears on the possible nature of the disease is summarized in Tables I, II and III.

TABLE I.—EXPERIMENTAL TRANSMISSION OF SERUM HEPATITIS TO MAN.

clinic is described. Chart II shows the chronology of these events, and indicates the occurrence of jaundice in the husbands of two women with jaundice after intervals of 66 and 104 days.

207 KY = 2.0 c.c. subcutaneously of Batch 207 KY serum given to 10 volunteers.

034 = 50 c.c. intravenously of Batch 034 serum given to 4 patients (*vide* Bradley, Loutit and Maunsell, 1944).

EP.Hep. = 1.25 c.c. subcutaneously of serum from case of epidemic hepatitis given to 6 volunteers.

*Not more than 40 individuals at risk.

CHART II.—Dates of onset of jaundice at a rheumatism clinic.

CONCLUSION

Post-transfusion jaundice has been of considerable importance during the war. It is an unnatural hazard and doubly tragic because of this and the way in which it has so frequently brought the surgeon's efforts to naught. The need for a method of preventing it without withholding transfusion is great. Furthermore, so long as the hazard of homologous serum jaundice exists we shall hesitate to apply extensively serum or immune globulin prophylaxis in measles, mumps, epidemic hepatitis, influenza and other virus diseases which may be amenable to attenuation or prevention by this method.

Lastly, and perhaps most important, this experience with homologous serum jaundice has shown that small quantities of blood, conveyed during therapy from person to person in a variety of ways, can incidentally carry disease. Whereas jaundice is a striking clinical sign and hepatitis easily diagnosed, less spectacular infections might, on occasion, be passed round by the same means without the accidental nature of the transmission being recognized. Parenteral and blood therapies have provided us with great advantages, but we must keep a watch on them in order to detect and eliminate, as soon as possible, any undesirable features tending to vitiate or discredit them.

Several experiments carried out by Oliphant suggested that the agent could be inactivated by ultraviolet light, but experiments by MacCallum *et al.* indicated that difficulties might arise in determining the suitable energy to be used and the duration of exposure. In their first experiment the supposedly suitable exposure failed to inactivate. In the second experiment the irradiation may have been effective, but when the serum was examined electrophoretically by Dr. R. A. Kekwick it was found that gross changes had occurred in the proteins. A very small residue of probably unchanged gamma globulin was detectable. Since the immune bodies in convalescent serum appear to be associated with the gamma globulin fraction this serum had been rendered useless for such a purpose. Even so, of the 10 recipients of this serum, one became jaundiced twenty-seven days after inoculation.

It has been suggested that very large pools would be safe because there would be sufficient immune bodies to neutralize any agent present. That such an event may occur has been shown by Oliphant, who inoculated a commercial pool of serum which contained serum of an individual taken four days before he became jaundiced (the total number of contributors to the pool was not stated). The jaundiced donor in this case was presumably suffering from infective hepatitis. This pool failed to produce hepatitis when injected subcutaneously or intravenously. Since the probability of neutralization occurring is unpredictable, this method does not seem safe. Though impracticable in wartime, the safest procedure would seem to be to process sera individually or at most small pools of two or three sera, thus limiting the number of recipients at risk if an icterogenic agent is present. If some idea could be obtained of the number of units of the agent that are neutralized by a given quantity of immune gamma globulin, the latter might be added to all pools as a routine.

SUMMARY

The available evidence suggests that the agent responsible for most cases of homologous serum hepatitis is not the same as that causing naturally occurring infective hepatitis.

The agent will pass through the usual filters which retain bacteria, but its actual size has not been determined. It is extremely resistant to heat and disinfectants, and no satisfactory method for the routine treatment of serum is known at present.

Dr. H. E. Magee: Two Cases of Homologous Serum Jaundice.

My remarks are concerned mainly with the history of two cases of homologous serum jaundice, treated with protein hydrolysates.

Intravenous alimentation with protein hydrolysates and glucose was used in the treatment of severe cases of starvation in Holland and in the German horror camps. The treatment was not a resounding success; it was also employed with a fair amount of success in the treatment of a few cases of advanced starvation in repatriated men from Germany in the spring and summer of 1945. I have already discussed the principles of treatment in a paper given to the Section of Medicine last year (*Proc. R. Soc. Med.*, 38, 388) and again in the Milroy Lectures given in February (*Brit. med. J.*, 1946 (i) 475). After the arrival of the first case of starvation in England in 1945, the Ministry of Health established emergency supplies of hydrolysates ready for administration at Headquarters in Whitehall and in the Regional Offices throughout the country.

On September 18, 1945, Dr. ap Simon of Park Prewett Hospital telephoned me saying that he had a case which he thought might benefit from intravenous alimentation and he gave me a history of the case. At first I doubted whether it was suitable because our experience, small as it was, had been confined to cases of plain starvation, and it was for such cases that the very limited supplies of hydrolysates were intended. However, when Dr. ap Simon informed me that the prognosis was hopeless, that the patient was comatose and had not retained any food for nearly a week, I asked my colleague, Dr. Adcock, to take a sufficient supply for the case straightaway to Park Prewett Hospital. The treatment was commenced the next day.

TABLE III.—ATTEMPTS AT "INACTIVATION" OF ICTEROGENIC SERA.

I. Heat: (1) Survived 56° C. for 1 hour—routine (2) Dried Y.F. vaccine-agent survived 1½ years at room temperature									
II. Triple ether extractions in the cold MacCallum, Stewart, Bradley				Pool B		10 recipients,	10 jaundice		
III. Ultraviolet light Oliphant				(1) (a) Ictero-genic Y.F. vaccine—untreated	...	10 recipients,	2 jaundice		
				(b) Vaccine exposed for 1 hour at 2,650 Å	...	10 recipients,	0 jaundice		
				1½ hours at 2,537 Å	...				
				(2) (a) Pool of pre-icteric sera—untreated	...	13 recipients,	2 jaundice		
				(b) Serum in (a) exposed for 45 minutes at 85%, 2,537 Å	...	11 recipients,	0 jaundice		
				(3) (a) Pool of pre-icteric serum—untreated	...	9 recipients,	1 jaundice		
				(b) Serum in (a) irradiated in thin quartz cell 2½ secs. by high energy, low-pressure water, cooled mercury lamp	...	20 recipients,	0 jaundice		
MacCallum				(1) (a) Pool B—untreated	...	14 recipients,	6 jaundice		
Stewart,				(b) 30 minutes at 80%, 2,537 Å	...	10 recipients,	2 jaundice		
Bradley				(2) (a) Pool B—untreated	...	4 recipients,	3 jaundice		
				(b) 30 minutes at 95%, 2,536 Å	...	10 recipients,	1 jaundice		
IV. Phenol: Pool K 60 convalescent measles serum—still active after contact with 0.25% phenol for fourteen months									
V. Tricresol: No evidence at present									
Possible methods of control:									
(1) Gamma globulin—Addition of known immune gamma globulin to pools									
(2) Very large-pools 50,000 donors									
Small pools 10 donors									
Very small pools, or single specimens									

In 1943 Oliphant *et al.* showed that an icterogenic agent was present during the pre-icteric and early icteric stages in the blood of individuals who developed hepatitis with jaundice as a result of the injection of certain batches of yellow fever vaccine containing human serum made in the U.S.A. At the same time MacCallum and Bauer in England were able to confirm previous theories as to the origin of yellow fever vaccine jaundice by showing that an icterogenic agent was present in a pool of supposedly normal human serum collected at a blood bank and used to make certain icterogenic batches of yellow fever vaccine. Further studies of such pools have shown that they can produce hepatitis when injected intradermally, subcutaneously, intramuscularly or intravenously, but not intranasally or *per os*. Different pools of proven icterogenicity have different attack rates. The size of the inoculum has, within certain wide limits, no effect upon the attack rate, duration of the incubation period or severity of the illness. The agent has been detected circulating in the blood of one recipient thirty-four days after inoculation and 60 days before the appearance of jaundice and in another recipient seven days after the appearance of jaundice, but not two months later. A single specimen of serum collected on the seventh day of jaundice from a presumably induced case produced hepatitis and jaundice when injected intranasally, though the original pool used as inoculum did not. Transmission of the disease to man by intranasal inoculation of nasopharyngeal washings collected in the pre-icteric and early icteric stages has been reported in West Africa by Findlay and Martin. This is a contradiction of the results obtained by intranasal injection of icterogenic serum pools, but the difference may be related to the state in which the agent is present in the pools. (No successful transmissions with nasopharyngeal washings from cases of naturally occurring infective hepatitis have been recorded.) It has not been possible to transmit the disease by oral administration of faeces from cases induced by the injection of icterogenic pools. All the results of the experimental inoculation by different routes of serum and other excreta serve to distinguish the usual form of homologous serum hepatitis from naturally occurring infective hepatitis.

The reinoculation, accidentally or experimentally, of individuals convalescent from either homologous serum hepatitis or infective hepatitis suggests that homologous but not heterologous immunity is usually produced by one attack of either disease. In fact, the suggestion has been made that a previous attack of the one disease makes the individual more susceptible to the other. No explanation is forthcoming for the results of Oliphant's experiments in cross-immunity unless he had by chance selected 10 individuals who were not susceptible to infective hepatitis.

There is at present no test which will detect the presence of the icterogenic agent in a suspected serum except observation of the result of injection of the serum into man. Therefore it is desirable to obtain some method of routine treatment of all sera which will inactivate the agent, if it is present in them, without destroying the essential properties of the serum. As can be seen in Table III, the agent is extremely resistant to heat at the temperature usually used for inactivation. The effect of higher temperatures has not been tested, but most sera will coagulate when heated above 60°C. Phenol in a concentration of 0.25% has also failed to inactivate the agent.

Several experiments carried out by Oliphant suggested that the agent could be inactivated by ultraviolet light, but experiments by MacCallum *et al.* indicated that difficulties might arise in determining the suitable energy to be used and the duration of exposure. In their first experiment the supposedly suitable exposure failed to inactivate. In the second experiment the irradiation may have been effective, but when the serum was examined electrophoretically by Dr. R. A. Kekwick it was found that gross changes had occurred in the proteins. A very small residue of probably unchanged gamma globulin was detectable. Since the immune bodies in convalescent serum appear to be associated with the gamma globulin fraction this serum had been rendered useless for such a purpose. Even so, of the 10 recipients of this serum, one became jaundiced twenty-seven days after inoculation.

It has been suggested that very large pools would be safe because there would be sufficient immune bodies to neutralize any agent present. That such an event may occur has been shown by Oliphant, who inoculated a commercial pool of serum which contained serum of an individual taken four days before he became jaundiced (the total number of contributors to the pool was not stated). The jaundiced donor in this case was presumably suffering from infective hepatitis. This pool failed to produce hepatitis when injected subcutaneously or intravenously. Since the probability of neutralization occurring is unpredictable, this method does not seem safe. Though impracticable in wartime, the safest procedure would seem to be to process sera individually or at most small pools of two or three sera, thus limiting the number of recipients at risk if an icterogenic agent is present. If some idea could be obtained of the number of units of the agent that are neutralized by a given quantity of immune gamma globulin, the latter might be added to all pools as a routine.

SUMMARY

The available evidence suggests that the agent responsible for most cases of homologous serum hepatitis is not the same as that causing naturally occurring infective hepatitis.

The agent will pass through the usual filters which retain bacteria, but its actual size has not been determined. It is extremely resistant to heat and disinfectants, and no satisfactory method for the routine treatment of serum is known at present.

Dr. H. E. Magee: Two Cases of Homologous Serum Jaundice.

My remarks are concerned mainly with the history of two cases of homologous serum jaundice, treated with protein hydrolysates.

Intravenous alimentation with protein hydrolysates and glucose was used in the treatment of severe cases of starvation in Holland and in the German horror camps. The treatment was not a resounding success; it was also employed with a fair amount of success in the treatment of a few cases of advanced starvation in repatriated men from Germany in the spring and summer of 1945. I have already discussed the principles of treatment in a paper given to the Section of Medicine last year (*Proc. R. Soc. Med.*, 38, 388) and again in the Milroy Lectures given in February (*Brit. med. J.*, 1946 (i) 475). After the arrival of the first case of starvation in England in 1945, the Ministry of Health established emergency supplies of hydrolysates ready for administration at Headquarters in Whitehall and in the Regional Offices throughout the country.

On September 18, 1945, Dr. ap Simon of Park Prewett Hospital telephoned me saying that he had a case which he thought might benefit from intravenous alimentation and he gave me a history of the case. At first I doubted whether it was suitable because our experience, small as it was, had been confined to cases of plain starvation, and it was for such cases that the very limited supplies of hydrolysates were intended. However, when Dr. ap Simon informed me that the prognosis was hopeless, that the patient was comatose and had not retained any food for nearly a week, I asked my colleague, Dr. Adcock, to take a sufficient supply for the case straightaway to Park Prewett Hospital. The treatment was commenced the next day.

The Park Prewett case was an Army Officer, aged 36, who on June 29, 1945, sustained simple fractures of the femur and the maxilla and a flesh wound of the leg with severe shock. He was given 1 pint each of plasma and blood. Ten days later he was transferred to Park Prewett. He then had a mild attack of bronchopneumonia but soon recovered. During this time he had been visited by a patient who became jaundiced on September 7. On September 13, seventy-six days after transfusion, evidence of hepatitis began to show and became more and more grave during the next five days. On September 18, the patient vomited dark blood and became comatose. Glucose was given by vein and rectum. On September 19, he was deeply comatose and very cyanotic. Treatment with protein hydrolysate was begun (500 c.c., equivalent to 25 g. protein, 200 calories by vein preceded by 500 c.c. of 5% or 10% glucose, 200 to 400 calories by vein). The treatment was continued until September 24, the patient receiving a total of 3,500 c.c. hydrolysate (175 g. protein, 700 calories) and 350 g. glucose (1,400 calories). The injected veins thrombosed. Improvement set in on 22nd and on 24th he was able to take food by mouth, a low fat, high protein diet. By October 4 he was practically free of symptoms. Convalescence was uneventful and he is now well.

A full report of this case was prepared by Dr. ap Simon and has since appeared in the *Lancet* (1946 (i) 492). I discussed the case subsequently with Dr. Bradley, and we arranged with Dr. Panton for the supplies of hydrolysates at Headquarters and in the Regions to be transferred to the Blood Transfusion Centres where a 24-hour service is in operation. These supplies are therefore available at call in the Transfusion Centres.

The second case was a married woman, aged 30, under the care of Dr. Williams. On November 9, 1945, an ectopic pregnancy ruptured. At operation in Llanelly Hospital she was given two pints plasma and one pint of her own blood recovered from the abdomen. On November 26 she was discharged well. On January 7, 1946, fifty-eight days after transfusion symptoms of liver damage set in and increased in severity during the next four weeks. She was readmitted to Llanelly Hospital on February 8 but deteriorated so rapidly that Dr. Williams was convinced she would die. He asked Dr. Watkin, Cardiff Blood Transfusion Centre, to see her. Her condition was very grave but she was not comatose; nausea, vomiting and continuous salivation and jaundice were marked. Dr. Watkin telephoned me on February 13, and I advised treatment with protein hydrolysate to begin at once, each dose to be preceded by 500 c.c. 5 or 10% glucose and to be given once or twice daily as he thought fit. I warned him of the likelihood of thrombosis and he gave 5,000 Toronto units of heparin before every infusion. Treatment began on February 14 when she was given by vein 400 c.c. 5-4% glucose followed by 500 c.c. hydrolysate twice. On each of 15th, 16th, 18th and 19th she was given 400 c.c. 10% glucose and 500 c.c. hydrolysate once. Improvement was apparent on 15th and by 20th she was able to take skimmed milk by mouth. Her appetite continued to improve but on 22nd it was decided to give more hydrolysate. During the infusion she had a severe rigor, vomited and then collapsed. She was given adrenaline and coramine and recovered after an hour. Improvement continued during the next three days, but soreness of the mouth, herpes and a scarlatiniform rash over the thrombosed sites of the venipunctures appeared on 25th and was general on 26th. On 27th the rash had gone and she was eating well, 1,400 to 1,600 calories a day. I saw her the next day and apart from slight jaundice and pain at the sites of injection she was quite well. Appetite and general condition improved until March 5, when she had a sudden flare-up of an old pyelitis which was practically over in forty-eight hours. By March 12 her appetite was very good and there was little jaundice. She has gone on improving and the last report I had, on March 21, said she was improving satisfactorily. During the six days of intravenous alimentation she received about 1,400 calories and the equivalent of 150 g. protein.

The Llanelly patient had many ups and downs. If only we knew the causes of the downs, it would enable us to have a better understanding of this condition and of how to treat it. Progress was not so satisfactory as in the Park Prewett case, but it should be noted that the latter received 3,500 c.c. hydrolysate in four days whereas the Llanelly case got 3,000 in six days. It may be that rapid administration from the start is the best method of treatment. I should be inclined to recommend this in any future case. The set-back in the Llanelly case on February 22 and the subsequent rash suggested a protein reaction, but the manufacturers have assured us that the hydrolysate is free from protein and from long-chain polypeptides.

Whipple (*Amer. J. med. Sci.*, 1946, 211, 149), who has done much fundamental work on protein regeneration, has shown that the 10 essential amino-acids, plus glycine, can be given by vein, or intraperitoneally for days and weeks on end to human patients, as the main or even the sole nutriment, and positive nitrogen balances and increases in body-weight have resulted. According to him, the unnatural isomers of the amino-acids are not toxic to man, but aspartic acid and especially glutamic acid are toxic when administered by vein. Casein hydrolysates like those used for these cases are relatively rich in glutamic acid. It may be that the Llanelly case was unusually sensitive to glutamic acid. Beattie (*Nature*, 1944, 153, 525) has shown that methionine alone is useful prophylactically and therapeutically in liver damage from various causes.

These digests are still in the experimental stage and more research requires to be done to bring them to the desired state of perfection. Nevertheless, there can be little doubt that the preparation used, with all its imperfections, has been mainly responsible for saving the lives of these two patients.

I have to thank Drs. ap Simon, Watkin and Williams and the Editor of the *Lancet* for their courtesy in permitting me to discuss these cases.

Professor John Beattie: The available evidence points to the conclusion that homologous serum jaundice is an infectious disease caused by an agent probably of a virus nature.

My group has been concerned with a study of the physiological and biochemical phenomena which appear during the acute and recovery phases of the disease. The disease is essentially an hepatic condition in which there are varying degrees of dysfunction and of destruction of hepatic tissue. In animals Mann has shown that signs of hepatic insufficiency do not appear until the total mass of the liver is reduced to around 20% of its normal value. If we can apply this conclusion to the disease we are studying it would appear that more than 80% of the liver may be thrown out of action—either because of disturbed function or anatomical destruction—during the acute phase of the disease. If hepatic tissue can be destroyed or rendered afunctional, to the extent suggested by Mann's experiments, before clinical and biochemical signs of hepatic insufficiency appear, it is obvious that the disease has taken hold and is progressing for some time before the critical level of insufficiency is reached.

There are some pieces of evidence which suggest that this may happen. In suspected cases of the disease admitted to hospital because of vague abdominal discomfort and slight hepatic enlargement and which later developed all the characteristic signs and symptoms, it was found on admission that a considerable loss of body-weight had already occurred varying from 2 to 10 kg., although anorexia had not developed to a degree sufficient to account for the weight loss. Nitrogen balance experiments demonstrated a marked negative nitrogen balance. The conclusion which we came to was that even before any clinical signs or symptoms—even the vaguest—had appeared, there was either an excessive destruction of body protein or alternatively that the rate of protein synthesis within the body had been reduced considerably below the normal rate of protein destruction. This state of negative nitrogen balance persisted during the acute phase of the disease and became positive with the return of appetite and other signs of clinical improvement. The positive balance was, however, due not to a reduction in the urinary nitrogen, but to an increase in nitrogen input. The rate at which the body-weight increased during the phase of positive nitrogen balance could be predicted with some degree of accuracy from the magnitude of the positive balance.

If we accept the hypothesis that homologous serum jaundice is a virus disease, we can interpret our findings along these lines. During the so-called incubation period of the disease, the virus protein is multiplying and obtaining the various specific amino-acids, which it requires to build its molecule, from the protein matrix of the body cells. If a sufficient number of liver cells are invaded by the virus, then a time will come when the liver cell cannot supply sufficient new protein for the general body needs. At that time and for some time before it the body must be in a state of negative nitrogen balance and protein requirements of the body must be met from the protein reserves in the tissues. Consequently weight must be lost. We can envisage this phase being completed without any clinical disturbance. When the virus continues to grow within the hepatic cell, a time will come when the virus will grow at the expense of the essential proteins of the cell itself and consequently necrosis takes place. The onset of clinical symptoms will date from the time when a sufficient number of liver cells are destroyed and a sufficient number rendered afunctional because of the presence of a large amount of virus body. If the process of virus growth is unchecked, the complete destruction of all the hepatic tissue takes place.

In the great majority of cases, the disease is checked, sometimes before icteric staining appears and sometimes only after a large portion of the liver tissue is destroyed. We may presume that the checking of the disease is due to the production of some specific antibody which is most likely to be of a protein nature. If this interpretation is correct, we can see that the nutritional state of the individual is a matter of some importance in determining the severity of the disease. When the protein reserves of the body are large, there will be more time for antibody to be produced before necrosis of the hepatic tissue reaches a critical level.

It must be emphasized here that this interpretation, while it does seem to fit the facts we have determined, cannot be considered as other than a tentative explanation.

We observed in severe or moderately severe cases material clinical benefit to follow the administration of large doses of methionine. In the less severe cases this benefit was not apparent to such a striking degree. We might therefore ask the question: How does methionine produce a clinical improvement? It is obvious that it cannot within a matter of a few hours or days produce a rapid regeneration of hepatic tissue. At present we incline to the view that methionine may effect clinical improvement in some part by its lipotropic action. The cells which are in process of necrosis around the intralobular virus are surrounded by a ring of cells packed with fat globules. Hence the cells are swollen and produce a mechanical obstruction to the free flow of blood to the centre of the lobule and also obstruct to some degree the bile capillaries. When methionine is given, fat is moved rapidly out of the hepatic cells and into the blood-stream. As this occurs, there is some degree of ketosis and ketone bodies appear in the urine. The final result is a rapid shrinkage of the liver and a fall in the serum bilirubin values. Nausea and vomiting, if present, disappear and there is a return of appetite.

In all probability this explanation is incomplete but it does explain why methionine is most effective when the liver is markedly enlarged and least effective when the liver is small, i.e. when necrosis is already extensive.

From the epidemiological point of view we came to the conclusion that both in this disease and in infective hepatitis, the patient was infectious for an unknown period before the onset of the first clinical symptoms. During this phase, the disease was already well established but symptoms had not appeared because (1) hepatic dysfunction and destruction had not proceeded to the stage where hepatic insufficiency developed, and (2) intrahepatic obstruction due to fat deposition had not occurred.

The Park Prewett case was an Army Officer, aged 36, who on June 29, 1945, sustained simple fractures of the femur and the maxilla and a flesh wound of the leg with severe shock. He was given 1 pint each of plasma and blood. Ten days later he was transferred to Park Prewett. He then had a mild attack of bronchopneumonia but soon recovered. During this time he had been visited by a patient who became jaundiced on September 7. On September 13, seventy-six days after transfusion, evidence of hepatitis began to show and became more and more grave during the next five days. On September 18, the patient vomited dark blood and became comatose. Glucose was given by vein and rectum. On September 19, he was deeply comatose and very cyanotic. Treatment with protein hydrolysate was begun (500 c.c., equivalent to 25 g. protein, 200 calories by vein preceded by 500 c.c. of 5% or 10% glucose, 200 to 400 calories by vein). The treatment was continued until September 24, the patient receiving a total of 3,500 c.c. hydrolysate (175 g. protein, 700 calories) and 350 g. glucose (1,400 calories). The injected veins thrombosed. Improvement set in on 22nd and on 24th he was able to take food by mouth, a low fat, high protein diet. By October 4 he was practically free of symptoms. Convalescence was uneventful and he is now well.

A full report of this case was prepared by Dr. ap Simon and has since appeared in the *Lancet* (1946 (i) 492). I discussed the case subsequently with Dr. Bradley, and we arranged with Dr. Pantton for the supplies of hydrolysates at Headquarters and in the Regions to be transferred to the Blood Transfusion Centres where a 24-hour service is in operation. These supplies are therefore available at call in the Transfusion Centres.

The second case was a married woman, aged 30, under the care of Dr. Williams. On November 9, 1945, an ectopic pregnancy ruptured. At operation in Llanelly Hospital she was given two pints plasma and one pint of her own blood recovered from the abdomen. On November 26 she was discharged well. On January 7, 1946, fifty-eight days after transfusion symptoms of liver damage set in and increased in severity during the next four weeks. She was readmitted to Llanelly Hospital on February 8 but deteriorated so rapidly that Dr. Williams was convinced she would die. He asked Dr. Watkin, Cardiff Blood Transfusion Centre, to see her. Her condition was very grave but she was not comatose; nausea, vomiting and continuous salivation and jaundice were marked. Dr. Watkin telephoned me on February 13, and I advised treatment with protein hydrolysate to begin at once, each dose to be preceded by 500 c.c. 5 or 10% glucose and to be given once or twice daily as he thought fit. I warned him of the likelihood of thrombosis and he gave 5,000 Toronto units of heparin before every infusion. Treatment began on February 14 when she was given by vein 400 c.c. 5-4% glucose followed by 500 c.c. hydrolysate twice. On each of 15th, 16th, 18th and 19th she was given 400 c.c. 10% glucose and 500 c.c. hydrolysate once. Improvement was apparent on 15th and by 20th she was able to take skimmed milk by mouth. Her appetite continued to improve but on 22nd it was decided to give more hydrolysate. During the infusion she had a severe rigor, vomited and then collapsed. She was given adrenaline and coramine and recovered after an hour. Improvement continued during the next three days, but soreness of the mouth, herpes and a scarlatiniform rash over the thrombosed sites of the venipunctures appeared on 25th and was general on 26th. On 27th the rash had gone and she was eating well, 1,400 to 1,600 calories a day. I saw her the next day and apart from slight jaundice and pain at the sites of injection she was quite well. Appetite and general condition improved until March 5, when she had a sudden flare-up of an old pyelitis which was practically over in forty-eight hours. By March 12 her appetite was very good and there was little jaundice. She has gone on improving and the last report I had, on March 21, said she was improving satisfactorily. During the six days of intravenous alimentation she received about 1,400 calories and the equivalent of 150 g. protein.

The Llanelly patient had many ups and downs. If only we knew the causes of the downs, it would enable us to have a better understanding of this condition and of how to treat it. Progress was not so satisfactory as in the Park Prewett case, but it should be noted that the latter received 3,500 c.c. hydrolysate in four days whereas the Llanelly case got 3,000 in six days. It may be that rapid administration from the start is the best method of treatment. I should be inclined to recommend this in any future case. The set-back in the Llanelly case on February 22 and the subsequent rash suggested a protein reaction, but the manufacturers have assured us that the hydrolysate is free from protein and from long-chain polypeptides.

Whipple (*Amer. J. med. Sci.*, 1946, 211, 149), who has done much fundamental work on protein regeneration, has shown that the 10 essential amino-acids, plus glycine, can be given by vein, or intraperitoneally for days and weeks on end to human patients, as the main or even the sole nutriment, and positive nitrogen balances and increases in body-weight have resulted. According to him, the unnatural isomers of the amino-acids are not toxic to man, but aspartic acid and especially glutamic acid are toxic when administered by vein. Casein hydrolysates like those used for these cases are relatively rich in glutamic acid. It may be that the Llanelly case was unusually sensitive to glutamic acid. Beattie (*Nature*, 1944, 153, 525) has shown that methionine alone is useful prophylactically and therapeutically in liver damage from various causes.

These digests are still in the experimental stage and more research requires to be done to bring them to the desired state of perfection. Nevertheless, there can be little doubt that the preparation used, with all its imperfections, has been mainly responsible for saving the lives of these two patients.

I have to thank Drs. ap Simon, Watkin and Williams and the Editor of the *Lancet* for their courtesy in permitting me to discuss these cases.

Professor John Beattie: The available evidence points to the conclusion that homologous serum jaundice is an infectious disease caused by an agent probably of a virus nature.

or communication" with a vessel in quarantine who did not forthwith repair to an appointed lazaret, vessel or place and then perform quarantine, were liable to various pains (including pains of death), penalties, fines, forfeitures and punishments.

Whilst the passengers and crew of any vessel under quarantine could have the assistance of any medical person they desired from the shore, such medical persons, if they communicated by contact with the sick, had to perform the same quarantine as the sick persons themselves (Clause XXV).

Moreover, when it became necessary for the Medical Attendant on the staff of the Superintendent of Quarantine to inspect the sick, he was required to keep his boat to windward of the vessel in which the sick were at a distance of not less than ten feet and if any patient, after being examined in this manner, was found to require special medical or surgical aid he was removed to a hospital ship. Apparently the last of these old hulks was the hospital ship "Fleming," which lingered on in Plymouth Sound until 1930.) The Quarantine Acts were not finally repealed until 1896 but long before then they had been regarded as a failure. As far back as 1849 the subject had been discussed by the General Board of Health for England and Wales (at that time the Central Health Authority for the country) and it was even then contended that quarantine could give but a false sense of security.

The General Board of Health was replaced in 1858 by the Privy Council as the Central Health Authority for England and Wales and in 1865 Sir John Simon, the Medical Officer of the Privy Council, in an official memorandum [1] on the subject of quarantine summed up heavily against such useless restrictions and paper plausibilities.

"A quarantine which is ineffective is a mere irrational derangement of commerce; and a quarantine of this kind which ensures success is more easily imagined than realized. Only in proportion as a community lives apart from the great highways and emporia of commerce, or is ready and able to treat its commerce as a subordinate political interest, only in such proportion can quarantine be made effectual for protecting it. In proportion as these circumstances are reversed, it becomes impossible to reduce to practice the paper plausibilities of quarantine. The conditions which have to be fulfilled are conditions of national seclusion."

In 1871 the Privy Council issued several Orders, under which Customs officers were empowered to visit and examine ships and to detain those infected or suspected to be infected with cholera. The ship had to be moored where the Customs officers directed and no person could land whilst the ship was so detained. The Customs had then to notify forthwith the local sanitary authority, who were empowered to visit and examine the vessel before it could enter port. Infected persons had to be removed to hospital and bedding and clothing disinfected or destroyed, the measure taken depending on the results of medical inspection without any undue detention of the ship.

Later in the year (1871) the Privy Council were succeeded by the Local Government Board as the Central Health Authority, and the passing of the Public Health Act, 1872, gave the Board power to constitute for the first time Port Sanitary Authorities either by designating one or by uniting two or more of the sanitary authorities (referred to as Riparian Authorities) whose district or part of whose district forms part of or abuts upon any part of a port or the waters of such port. Their jurisdiction was over all the waters within the limits of the port and also the whole or such portion of any Riparian Authorities as might be specified, and the Local Government Board had powers to assign to Port Sanitary Authorities any powers, rights, duties, capacities, liabilities and obligations under the Sanitary Acts.

The expenses incurred by a Port Sanitary Authority were defrayed out of a common fund contributed to by the Riparian Authorities included in the Port Sanitary Authority in such proportions as the Local Government Board thought just, a subject which will again be referred to.

In a way a dual system of control then arose for although the Quarantine Act, which was administered by the Privy Council, was rapidly falling into disuse quarantine was still practised to a limited extent for yellow fever. But this was not primarily on medical grounds but solely with the view of relieving our Maritime commerce from disabilities which would otherwise have been imposed upon it by other countries in which quarantine was regarded as an essential part of their health administration.

The last occasion when a vessel arrived with yellow fever actually on board was in 1865 [2]. On September 9 of that year the sailing barque "Hecla" reached Swansea from Cuba with three men suffering from yellow fever. Deaths had occurred during the voyage, but the disease was not declared when the vessel arrived. The weather at the time was exceptional and the heat is described as being almost tropical. Between September 15 (i.e. six days after her arrival) and October

¹No exhaustive search has been possible but from the records consulted the only Quarantine Station or Hospital on an island in the United Kingdom was on the Flat Holm Island in the Bristol Channel (about three miles to the southwest of the entrance to the Cardiff Docks). It is not clear when the station was first established but the arrangements are referred to in the Annual Report of the M.O.H. of Cardiff for 1889. A crematorium was added in 1893 but landings could only be effected in fine weather and the Hospital was finally closed in 1933.

Progress and Problems in Port Health Administration

By P. G. STOCK, C.B., C.B.E., M.B., F.R.C.P., Hon.F.R.C.S.Ed., D.P.H.

(President of the Section of Epidemiology and State Medicine)

INTRODUCTION.—About one hundred years ago—to be exact, on September 15, 1849—a letter appeared in the *Lancet* signed "Pater", urging the formation of a society to study epidemic disease. The ravages of cholera had recently carried off some 50,000 to 60,000 of the population of these Islands and "there was abroad an earnest desire to render another visitation of this disease, if not preventable, less disastrous in its results". The Epidemiological Society of London was founded in the following year (1850) becoming in 1907, on the amalgamation of various medical societies, the Epidemiological Section of the Royal Society of Medicine and in 1913 the Section of Epidemiology and State Medicine.

Amongst the many distinguished Presidents who preceded me was Dr. Richard Reece, who occupied the Chair in 1922/23 but died from influenza and overwork the following year. Reece was then Senior Medical Officer in the newly-formed Ministry of Health and chose as the subject for his Presidential Address "Progress and Problems in Epidemiology" (*Proc. R. Soc. Med.*, 1923, 16, Section Epidemiology, p. 35). I am convinced, however, that since his early days in the Port of London, before he joined the staff of the old Local Government Board, Reece's greatest interest lay with the welfare of those who "go down to the sea in ships", and consequently to everything that pertained to port health administration.

As it was under Reece's guidance that I had the honour to join this Section when I was a newly-appointed member of his staff, and had no conception that in the course of time I should succeed either to the post he held at the Ministry or to this Presidential Chair, I trust you will bear with me in paying this brief tribute to one of your former Presidents and for choosing as the subject for my Presidential Address to-day "Progress and Problems in Port Health Administration".

I. MARITIME TRAFFIC

The last Quarantine Act in this country was passed in 1825 and, whilst consolidating and modifying the Acts previously in force, it still enjoined detention and strict isolation

Under Clause II of the Act the places appointed for the performance of quarantine were Standgate Creek; Whitebooth Roads, between Hull and Grimsby; Bromborough Pool or Milford Haven; Motherbank near Portsmouth; St. Just's Pool within the mouth of the Harbour of Falmouth; King Road and Portshute Pill; Inverkeithing Bay (Firth of Forth); and Holy Loch in the Firth of Clyde. A number of places were similarly appointed for vessels bound to Ports in Ireland.

for specified periods of persons coming from ports considered to be infected, regardless of whether actual cases had occurred; and if cases occurred on the ship during the quarantine period an indefinite prolongation of the quarantine resulted. Various places were appointed for vessels to perform quarantine and any persons having "any intercourse

or communication" with a vessel in quarantine who did not forthwith repair to an appointed lazaret, vessel or place¹ and then perform quarantine, were liable to various pains (including pains of death), penalties, fines, forfeitures and punishments.

Whilst the passengers and crew of any vessel under quarantine could have the assistance of any medical person they desired from the shore, such medical persons, if they communicated by contact with the sick, had to perform the same quarantine as the sick persons themselves (Clause XXV).

Moreover, when it became necessary for the Medical Attendant on the staff of the Superintendent of Quarantine to inspect the sick, he was required to keep his boat to windward of the vessel in which the sick were at a distance of not less than ten feet and if any patient, after being examined in this manner, was found to require special medical or surgical aid he was removed to a hospital ship. Apparently the last of these old hulks was the hospital ship "Flamingo," which lingered on in Plymouth Sound until 1930.) The Quarantine Acts were not finally repealed until 1896 but long before then they had been regarded as a failure. As far back as 1849 the subject had been discussed by the General Board of Health for England and Wales (at that time the Central Health Authority for the country) and it was even then contended that quarantine could give but a false sense of security.

The General Board of Health was replaced in 1858 by the Privy Council as the Central Health Authority for England and Wales and in 1865 Sir John Simon, the Medical Officer of the Privy Council, in an official memorandum [1] on the subject of quarantine summed up heavily against such useless restrictions and paper plausibilities.

"A quarantine which is ineffective is a mere irrational derangement of commerce; and a quarantine of this kind which ensures success is more easily imagined than realized. Only in proportion as a community lives apart from the great highways and emporia of commerce, or is ready and able to treat its commerce as a subordinate political interest, only in such proportion can quarantine be made effectual for protecting it. In proportion as these circumstances are reversed, it becomes impossible to reduce to practice the paper plausibilities of quarantine. The conditions which have to be fulfilled are conditions of national seclusion."

In 1871 the Privy Council issued several Orders, under which Customs officers were empowered to visit and examine ships and to detain those infected or suspected to be infected with cholera. The ship had to be moored where the Customs officers directed and no person could land whilst the ship was so detained. The Customs had then to notify forthwith the local sanitary authority, who were empowered to visit and examine the vessel before it could enter port. Infected persons had to be removed to hospital and bedding and clothing disinfected or destroyed, the measure taken depending on the results of medical inspection without any undue detention of the ship.

Later in the year (1871) the Privy Council were succeeded by the Local Government Board as the Central Health Authority, and the passing of the Public Health Act, 1872, gave the Board power to constitute for the first time Port Sanitary Authorities either by designating one or by uniting two or more of the sanitary authorities (referred to as Riparian Authorities) whose district or part of whose district forms part of or abuts upon any part of a port or the waters of such port. Their jurisdiction was over all the waters within the limits of the port and also the whole or such portion of any Riparian Authorities as might be specified, and the Local Government Board had powers to assign to Port Sanitary Authorities any powers, rights, duties, capacities, liabilities and obligations under the Sanitary Acts.

The expenses incurred by a Port Sanitary Authority were defrayed out of a common fund contributed to by the Riparian Authorities included in the Port Sanitary Authority in such proportions as the Local Government Board thought just, a subject which will again be referred to.

In a way a dual system of control then arose for although the Quarantine Act, which was administered by the Privy Council, was rapidly falling into disuse quarantine was still practised to a limited extent for yellow fever. But this was not primarily on medical grounds but solely with the view of relieving our Maritime commerce from disabilities which would otherwise have been imposed upon it by other countries in which quarantine was regarded as an essential part of their health administration.

The last occasion when a vessel arrived with yellow fever actually on board was in 1865 [2]. On September 9 of that year the sailing barque "Hecla" reached Swansea from Cuba with three men suffering from yellow fever. Deaths had occurred during the voyage, but the disease was not declared when the vessel arrived. The weather at the time was exceptional and the heat is described as being almost tropical. Between September 15 (i.e. six days after her arrival) and October

¹No exhaustive search has been possible but from the records consulted the only Quarantine Station or Hospita on an island in the United Kingdom was on the Flat Holm Island in the Bristol Channel (about three miles to the south-west of the entrance to the Cardiff Docks). It is not clear when the station was first established but the arrangements are referred to in the Annual Report of the M.O.H. of Cardiff for 1889. A crematorium was added in 1893 but landings could only be effected in fine weather and the Hospital was finally closed in 1933.

13, 22 cases occurred in Swansea in which the diagnosis of yellow fever seemed fairly certain, and 7 other cases in which the circumstances of exposure and the character of the attack led to a more or less strong suspicion that the illness was of the same nature. Of the cases diagnosed as yellow fever, 15 died and 7 recovered. Of the doubtful cases, 1 died and 6 recovered.¹

After the creation of Port Sanitary Authorities the system² depended essentially on medical inspection and the detention of a vessel only so long as was necessary to inspect those on board, to deal with the sick and carry out any necessary measures of disinfection.

The machinery set up under the Quarantine Acts for obtaining information as to health conditions on vessels from foreign was made use of for dealing with all diseases on incoming ships, and the "quarantine" questions which Customs officers were required to put to the Masters of vessels from foreign were continued as part of the routine in port sanitary districts, and Customs officers continued to visit, examine and detain ships. Under the Public Health Act, 1875 (Sections 130 and 134), powers were given to the Local Government Board to make regulations in regard to cholera and such other diseases, both on land and on the high seas, within three miles of the coast.

The first survey of the port and riparian sanitary districts by medical inspectors of the Local Government Board was carried out in 1886 and in consequence of the rapid diffusion of cholera throughout Russia in the summer of 1892 an emergency survey of the chief English ports was instituted. There were then 60 Port Sanitary Authorities in England and Wales and some 60 or 70 Riparian Authorities where there was shipping, but the old river ports of Tudor times such as Cambridge, Norwich, Oxford and York had lost their importance. In consequence of the unsatisfactory character of the then current arrangements in many of the districts visited, and in view of the continued prevalence of cholera in Europe a more detailed and deliberate survey of the whole coastline was started early in 1893 and completed in 1894.

Only a general summary of the findings can be attempted here but the Report [3] on the survey which was published in 1895 is full of interest. In his introduction Sir Richard Thorne, the Medical Officer³ to the Local Government Board, stated that when the survey was started (in 1892) it was found that in only one-third out of a total of 60 Port Sanitary Districts could the general administration be regarded as satisfactory and efficient but by the time the more detailed survey was completed the majority of the port and riparian districts were fairly well organized, so far as action under the cholera orders was concerned.

"For the purposes of cholera some means of hospital isolation was from the first found in 44 out of the 60 ports, and in 9 others it was provided after the inspector's visit. Ambulance boats were available in a number of the more important ports; provision existed in the great majority of the ports for the destruction by burning, or the disinfection, of clothing, &c.; and, with but few exceptions, some arrangements had been made as to the emptying of water-tanks on board ship, the provision of a proper water supply, and the pumping of bilges. The arrangements for the medical inspection of vessels and of persons, under the Board's Orders, were found to be satisfactory in all but five port districts. He added that in certain of them, notably, the ports of London, the River Tyne, Hull and Goole, Southampton, Weymouth, Plymouth, Bristol, Cardiff, Barry-and-Cadoxton, Swansea, and Liverpool, the arrangements were not only highly satisfactory in themselves, but they were carried out with a devotion to duty on the part of many of the Medical Officers of Health, such as must be regarded as having largely contributed to the marked success with which imported cholera was controlled at nearly all English ports during 1892 and 1893."

Demands were made at the time to revive Quarantine against infected ports but were firmly refused, and Sir Richard Thorne pointed out that:

"Port or Riparian Sanitary Authorities have imposed upon them the duty of so dealing with ships, either infected with cholera or arriving from places infected with cholera, that the sick shall be placed in hospital; that those suspected of cholera shall be detained for a limited period so that the nature of their illness may be ascertained; that certain sanitary measures such as efficient disinfection of vessels shall be carried out; and that prior to the landing of healthy persons their addresses at the places of destination to which they are travelling shall be obtained. Should cholera succeed in passing this outer line of defence, trust is placed for the prevention of its spread, in the general sanitary administration of the country."

As already stated, the quarantine enactments were finally abolished by the Public Health Act of 1896, which gave the Local Government Board power to enforce any Regulations made by them under the Public Health Act of 1875, with the assistance of the officers of Customs and Coastguards, as well as other Authorities. The Public Health (Ports) Act of 1896 enabled the Board to assign to Port Sanitary Authorities, powers

¹ See also the case of the "Sea Rambler" which arrived in the River Tyne in September 1936 from West Africa.

Ann. Rep. C.M.O., Min. of Health, 1936, p. 195.

² It was not, however, until the International Sanitary Conference of Vienna in 1874 that such a system rather than the old form of quarantine was accepted by a majority of the delegates.

³ The designation "Chief Medical Officer" was first used when the Ministry of Health replaced the Local Government Board in 1919.

under the Infectious Diseases (Prevention) Act and a series of General Regulations dealing with Cholera, Yellow Fever and Plague were issued by the Board. The passing of the Infectious Disease (Notification) Extension Act of 1899 made the notification of the more serious infectious diseases compulsory in every urban, rural and port sanitary district in England and Wales.

Another landmark was the formation of the Association of Port Sanitary Authorities¹ in 1898, when, during a conference of the Royal Sanitary Institution in Birmingham, representatives of the Port or Riparian Sanitary Authorities of Cardiff, Dover, Hull and Goole, Manchester, Newport, the River Tyne and Yarmouth met and started the Association.

The spread of plague to Europe in 1899 led to the International Sanitary Convention in 1903 and to implement this Convention, the Local Government Board issued, in 1907, a fresh series of Regulations (which had chiefly to be carried out by Port Sanitary Authorities) in regard to cholera, yellow fever, and plague on ships arriving from foreign countries; and as to cholera and plague on outward bound and coasting ships in the event of this country becoming infected by one or other of these diseases.

These Regulations took cognizance of the part played by rats in the spread of plague which had then been established, and in 1909 the Board started the issue of a "Weekly Record" of reported occurrences of plague, cholera and yellow fever (in ports at home and abroad) for the information of Port Medical Officers of Health. At first it was only neostyled and was a very incomplete affair, but the scope was gradually extended and in 1919 was printed and an extended distribution made.

The Regulations of 1907 were the last published by the Local Government Board as, owing to the War of 1914-18, an amended series drawn up to implement the International Sanitary Convention of 1912 was never issued.

At the end of the war the whole question of Port Health Administration was carefully reviewed and it was considered desirable to take special steps for guarding against the introduction of disease in view of the prevalence on the Continent of smallpox, typhus, relapsing fever and the increased risks to which this country was exposed by the amount of movement which the close of the war and demobilization were likely to produce.

It was recognized that the extended services which Port Sanitary Authorities would be required to provide were for the benefit of the country generally and not merely of the particular locality in which the ports were situated and a decision was reached—perhaps long overdue—that expenditure on efficient Port Sanitary Administration should be partially met by the Exchequer.

Regulations under which the Ministry of Health (which had then replaced the Local Government Board) would pay grants were issued in 1920 and authorized 50% of the approved expenditure in respect of the whole work of Port Sanitary Administration. This was defined as including expenditure on medical and other staff, provision and maintenance of isolation hospitals, disinfection and disinfection stations, the provision of facilities for chemical and bacteriological investigations, transport for the boarding of vessels, the administration of the Foreign Meat and Unsound Food Regulations, the work undertaken by Port Sanitary Authorities in the execution of the Public Health (Shellfish) Regulations, 1915, or otherwise in the supervision of shell fisheries and any other services required or approved by the Ministry.

At the same time, the Minister issued the Port Sanitary Authorities (Infectious Diseases) Regulations, 1920, which placed new responsibilities on these Authorities and their Medical Officers of Health in addition to those already imposed by the Cholera, Yellow Fever and Plague Regulations of 1907, which continued to apply to these diseases.

In certain circumstances, when the presence of infectious disease on a ship was suspected, a more extended medical examination of persons entering the country was required than had been undertaken hitherto. The Medical Officer of Health was empowered to board any ship for the purpose of the Regulations and to cause the ship to be brought to, and, if necessary, moored or anchored in, some safe and convenient place while it was visited and examined. In deciding whether he should use his powers to board a particular ship and examine persons on board, the Medical Officer of Health had to a large extent to exercise his discretion but in the covering circular to the Regulation the Minister expressed the view that the fact that a vessel during the period of *three* weeks before its arrival in port, had sailed from, or called during the voyage at, a foreign port or country in which dangerous infectious disease is known to be prevalent, would constitute reasonable ground for such action being taken.

Incidentally the covering circular pointed out that: "The more common infectious

¹ Now the Association of Port Health Authorities of the British Isles.

diseases such as scarlet fever and measles did not, in the Minister's opinion, save in exceptional instances, call for special action."

The Regulations authorized measures to be taken against other infectious diseases, notably typhus and smallpox, which in some respects were comparable to those required under the old Regulations (1907) for cholera, yellow fever and plague.

On the issue of the 1920 regulations, an extended survey of the Port and Riparian Sanitary Districts was carried out by a team of medical officers of the Ministry working under Dr. Reece, the inspections being followed in due course by conferences with each of the Sanitary Authorities concerned when the new Regulations and matters requiring attention were discussed.

These inspections also afforded opportunities for discussion with Port Medical Officers of Health of questions connected with the medical inspection of aliens for which they had become responsible at the Ports approved, by the Secretary of State, for the landing of aliens. (The cost of this service falls on the Exchequer.)

There were then 60 Port Sanitary Authorities and some 40 Riparian Authorities in England and Wales at which there was shipping, but in 1922, the Riparian Authorities of Dover and Folkestone were made Port Sanitary Authorities with jurisdiction over certain land areas in the immediate vicinity of the harbours.

During these inspections special attention was paid to the position of the mooring stations required under the Cholera, Yellow Fever and Plague Regulations of 1907 and the information then collected eventually led to the modifications introduced by the Port Sanitary Regulations of 1933. In the past sentimental consideration had frequently resulted in the selection of remote and often inconvenient places for mooring stations and one in the Bristol Channel was so unfortunately sited that a vessel proceeding there, before the days of wireless, might, in foggy weather, neither be seen from nor able to signal to the shore.

It may well be claimed that the issue of the new Regulations and the 50% grant, which enabled them to be carried out, together with the series of visits and conferences raised the whole standard of Port Health Administration and gave many Port Medical Officers of Health the opportunity to attain the state of efficiency they desired.

Probably the most important matter dealt with in the 1920 Regulations was the prevention of the danger of the spread of infectious diseases by vermin, especially by the deratization of ships. Towards the close of the (1914-18) war the possibility of plague being introduced into this country by infected rats occasioned anxiety. The subject is dealt with at length in a paper by Reece, which is printed in the Chief Medical Officer's Report for 1919-20, and appended to the paper are tables showing the number of vessels that arrived at Ports in England and Wales from 1895 to 1920 on which plague or suspected plague among men and rodents had occurred on the voyage. Time and space do not permit of the tables being brought up to date in this paper but the short reference seems pertinent as the facts set out were one of the factors which led up to the 1920 Regulations. Sea-borne commerce had been disorganized by war conditions and such anxiety as existed was not lessened by the increasing "ratty" condition of ships. Much of the merchandise which had accumulated at certain ports abroad afforded excellent opportunities for the harbourage of rats as well as ample food and facilities for nesting and breeding. Owing to the shortage of vessels and the necessity for avoiding all delays, ships had to be turned round as quickly as possible and the six-monthly deratization of ships which had been recommended in the International Sanitary Convention of 1912 and which, prior to the war (1914-18), was becoming usual throughout the world, fell into abeyance and there were many indications that the rat population of the Mercantile Marine had vastly increased. To give an extreme example after the fumigation of the S.S. "Khiva," with sulphur candles, in the Royal Albert Docks on January 6, 1920, nearly 1,500 rats were found dead and 35 loads of refuse were removed from the holds. Other countries were faced with the same problem for which some authorities considered complete fumigation of the ship was the only panacea.

The United States incorporated in their 1920 Quarantine Regulations a definite requirement that all vessels engaged in trade with foreign ports should be fumigated simultaneously in all parts either with sulphur dioxide gas or hydrogen cyanide. Early in 1922 these requirements were more strictly enforced and the American Public Health Authorities insisted that even the first and second class passenger accommodation of our large transatlantic liners should be included. Shipowners were then faced with the alternatives of complying with these Regulations or having their vessels quarantined on arrival in American ports—with the consequent enormous loss on "demurrage". To fumigate the passenger accommodation with sulphur dioxide gas, with the consequent damage to fittings and the loss of time required to make good, was held on economic

grounds, to be out of the question, the practical alternative being the use of hydrogen cyanide, a method employed by U.S. Quarantine Authorities since 1913.

The first vessel to be deratized with sulphur dioxide¹, at an English Port (the River Tyne) was the S.S. "Royal Dane" on December 22, 1899, but hydrogen cyanide had not been employed until Cunard Liner "Scythia" (19,730 tons gross register) was fumigated throughout at Liverpool on March 17, 1922. The long story of the fumigation of ships is outside the scope of this address and only occasional references can be made, but to give some idea of the extent to which fumigation was then being practised in America, the following figures are of interest. In the Port of New York during the twelve months ending June 30, 1922, 1,425 vessels with a total tonnage of 4,671,292 tons and an average tonnage of 3,418 were fumigated. The total rats recovered after fumigations was 6,925 or an average of only 4.8 rats per vessel.

Dr. Richard Reece and Surgeon-General H. Cumming, Quarantine Station, Craney Island, U.S.A., August 1922.

As it was considered desirable that inquiries on the whole question should be made in America, Dr. Reece and myself were sent to the United States in August 1922 to confer with the Surgeon-General of the Public Health Service, Dr. Hugh Cumming, and his staff, and to investigate their methods of fumigation. As a result of this visit, arrangements were made whereby certificates of Fumigation issued by certain Port Sanitary Authorities, approved by the Minister of Health, would be accepted by the Quarantine Authorities of the United States. The Port Medical Officers of Health of Bristol, Cardiff, Hull and Goole, Liverpool, London, Manchester, Southampton and Swansea (and subsequently Newport, Barry, Falmouth and Sunderland) were authorized to issue the special certificates (Form Port 10) and in November 1922 instructions were issued by the Minister in regard to the fumigation of vessels to comply with the requirements of the U.S.A.

That the part rats play in the spread of plague was fully realized in this country is illustrated by the following extract from a Circular (No. 374) which was issued by the Ministry of Health in January 1923 with the object of drawing the attention of County Councils to the need for delegating, to Port and Riparian Authorities, their jurisdiction under the Rats and Mice Destruction Act of 1919. This Act applies to vessels and gives Port Sanitary Authorities additional powers for dealing with vessels infested with rats, though experience has shown that the application of the Act to a particular vessel is sometimes difficult. In urging such delegation, the Ministry pointed out:

"Among the more important functions of Port and Riparian Sanitary Authorities under the Public Health Acts is the prevention of the introduction and spread in this country of ship-borne plague. For this purpose it is desirable that, in addition to their powers under the Public Health Acts, they should be able to take measures under the Rats and Mice (Destruction) Act, 1919, for the destruction of rats both on board ship and also on the quays, wharves and warehouses abutting upon the port."

Section 103 of the Quarantine Regulations of the United States (1920), which deals with the routine fumigation of vessels, was revised in January 1923, so as to allow for the extension of the period of six months in the case of vessels complying with the following conditions:

- (1) Vessel constructed so as not to favour or encourage the harbourage of rats.
- (2) Vessel plying regularly between ports not infected with plague.
- (3) Vessel regularly carrying no cargo, or cargo of such nature, or so packed or stowed, that it cannot serve as rat food or rat refuge.
- (4) Vessel has been regularly certified as loading in stream from rat-free lighters, or as complying with the regulations relative to fending off from docks, proper use of guards on lines and hawsers, raising or guarding of gangways and ladders, and docking at rat-free docks or wharves.

¹Liquid sulphur dioxide in cylinders was used.

The possibilities of rat-proofing continued to receive attention in the United States and the publication of an article on the rat-proofing of vessels in the Public Health Reports for July 17, 1925, aroused such widespread interest, especially among shipbuilders and shipowners, that the article was translated subsequently into several languages. A second and larger edition was published in December 1926.

Writing in his Annual Report for 1927, Sir George Newman stated:

"Though rat-proofing on shore is now a recognized practice the same cannot be said in regard to the application of the principles of rat-proofing in ships. Yet this is a matter which merits the serious consideration of naval architects, shipbuilders and shipowners. There can be little doubt that when the new International Sanitary Convention comes into operation the rat-proof ships will be at a great advantage over others when the question of the issue of a deratization exemption certificate has to be decided. It is frequently difficult and expensive, and it may be impossible, to make existing buildings or ships fully rat-proof, though many improvements can be effected in this direction by practical attention to minor details. In new construction, however, whether of buildings or ships, the application of the principles of rat-proofing should be neither difficult nor expensive and will fully repay any additional cost incurred."

A few Port Medical Officers of Health took the greatest interest in rat-proofing—notably Dr. Maurice Williams of Southampton—and a certain amount of rat-proofing was done on British vessels such as those of the Cunard S.S. Company—but it is the tramp rather than the mail steamer that carries plague. A third edition [†] of the American Memorandum was published in 1931 which covered all phases of rat-proofing as applied to ships both new and old, and copies were sent to the Medical Officers of Health of the Ports approved for the issue of Deratization and Deratization Exemption certificates. A further Report on Rat-proofing of new ships was published in 1939.

The benefits claimed in the U.S.A. from rat-proofing are summarized in a paper published in their Public Health reports for December 24, 1943, and when visiting the Quarantine Station, New York, in August 1943, it was learnt that it had never been necessary to fumigate a single vessel for the destruction of rats which had been constructed and structurally maintained in accordance with the rat-proofing specifications of the United States Public Health Service.

In June 1944 the Ministry of War Transport issued a memorandum on the rat-proofing of new ships and there seems little doubt that more and more attention will be paid to this method of combating the menace of rat plague.

Whilst Port Health Authorities in this country probably now regard rat-plague and smallpox as public enemies No. 1, they have many other responsibilities and the International Agreement of Brussels¹, for securing the gratuitous treatment at seaports of seamen when suffering from venereal disease, which was ratified by this country in 1925, added another to the list.

The next great advance resulted from the International Sanitary Convention of 1926 which was signed by the representatives of 66 countries and subsequently ratified by 44. It provides for the *immediate* notification by Governments to other Governments and to the Office International d'Hygiène publique of cases of plague (*including rodent plague*), cholera, yellow fever, epidemic typhus and smallpox, the last two diseases now being included in an International Sanitary Convention for the first time. When the formal conference was held in Paris to consider the draft revisions which had been prepared by the Office International, delegates still had in mind the disastrous pandemic of influenza in 1918-19 but a proposal to include influenza among the diseases dealt with in the Convention was not accepted, though subsequently the severe outbreak of dengue which occurred in Greece and other Mediterranean Countries in 1928 led to the International Convention for Mutual Protection against Dengue Fever of 1934.

The Convention, however, settled the much-disputed question of the procedure to be followed for dealing with the rat population in ships and preventing the spread of plague. Briefly, all vessels of signatory countries, except those engaged in national coast-wise trade, must be inspected at regular intervals of six months, to ascertain whether there are on board more than a minimum of rats. Any vessel on which there is evidence that the rat population is in excess must be subjected to deratization and a "Certificate of Deratization" on an approved form must be issued by the competent Authority. If, on the other hand, there is little or no evidence of rats in any vessel at the time of inspection a "Certificate of Exemption from Deratization" likewise on an approved form, must be granted. These Certificates will be recognized in the ports of other countries which have ratified the Convention and, in the absence of the occurrence of special circumstances such as plague amongst the rats on board, will exempt vessels from further fumigation during the six months following the issue of the Certificate.

¹ This agreement, which was initiated by the British Delegate, Sir George Buchanan, in May 1920 was drawn up by the Permanent Committee of the Office International d'Hygiène publique and after circulation to Governments by the Belgian Government, was signed at Brussels on December 1, 1924.

To implement these requirements the Permanent Committee of the Office International d'Hygiène publique drew up an international form of certificate. This was adopted and issued—as form Port II—with an explanatory memorandum to the Port Medical Officers whom the Minister of Health had authorized to grant such certificates. To provide more fully for the application of the relative article (No. 28) of the new Convention the Public Health (Deratization of Ships) Regulations were issued in October 1929. And, to ensure a reasonable degree of uniformity at the designated ports in England and Wales provisional standards for the fumigation of ships for the destruction of rats were issued. At that time 16 ports had been approved (and duly notified to the Office International) for the issue of Certificates and the naval ports of Chatham-Sheerness, Devonport and Portsmouth were also designated, at the request of the Admiralty, for the issue of Certificates to naval vessels.

During 1927-30 an unusual number of vessels arrived with rat-plague or suspected rat-plague on board. As an instance the case of the S.S. "Plutarch" may be quoted, which has an additional interest as this was the first occasion on which a loaded ship was fumigated in this country with HCN. The "Plutarch" arrived in the Port of London in June 1927 with a cargo of grain from the River Plate and during the early stages of unloading, dead rats were uncovered which, on bacteriological examination, were found to be infected with plague. Unloading was stopped and on my advice the vessel was fumigated throughout with hydrogen cyanide, the bulk of the cargo being still on board. After prolonged ventilation, unloading was completed and the vessel again fumigated. Two hundred and twenty-six dead rats were found after the first fumigation and five after the second, the inference being that the first fumigation had much reduced the risk of plague-infected rats escaping from the ship to the shore.

As another example the case of the S.S. "Somali" may be quoted. This vessel arrived in the Port of London on July 1, 1937, from the Far East with a mixed cargo. Two hundred rats were stated to have been caught during the voyage although the vessel was in possession of a deratization certificate issued at Kobe on April 28 following fumigation of the partly unloaded vessel with a mixture of carbon monoxide and carbon dioxide. An unusual mortality amongst the rats on board was discovered whilst the cargo was being discharged at a pontoon, and specimens sent for bacteriological examination on July 5 suggested the presence of plague infection. The unloading of the cargo was accordingly stopped and the vessel was fumigated throughout with hydrogen cyanide, the remainder of the cargo being discharged into lighters. As a result of the fumigation no less than 420 rats were recovered and after the unloading had been completed the vessel was again fumigated with hydrogen cyanide when a further 103 dead rats were found. The loaded barges into which the cargo had been discharged were also fumigated with hydrogen cyanide.

In the following year the Ministry of Health issued a Memorandum (revised in 1937) on the fumigation of ships with hydrogen cyanide and the procedure necessary to ensure success and to avoid accident. The Mercantile Marine Department of the Board of Trade also issued a notice (No. 94 of 1928) to shipmasters based on the Ministry's Memorandum.

The Health Committee of the League of Nations and the Permanent Committee of the Office International d'Hygiène publique also set up an expert Commission on the fumigation of ships under the Chairmanship of Surgeon-General Cumming to study in detail some of the problems arising in connexion with the fumigation of ships with hydrogen cyanide and more particularly the fumigation of ships in cargo. The more important conclusions of this Commission were: That the time had not yet arrived when one particular method for the fumigation of ships to the exclusion of all other methods could be recommended, but that the indiscriminate spraying of liquid HCN should not be practised and that neither the liquid acid nor other forms of cyanide should ever be poured directly on to bedding, carpets, &c. If carefully carried out, the fumigation of a loaded ship with HCN by the methods in use would account roughly for 80% of the rats, but various expedients must be adopted to reach rat harbourages in the lower parts of a ship under the cargo. The Commission recorded that no indications had been obtained of any injury to health or of deterioration of food values resulting from the consumption of fumigated food, but further investigations were desirable. With regard to the danger to fumigators working with high concentrations of HCN, they recommended that an oxygen breathing apparatus should be used instead of a gas mask.

Finally, the Commission pointed out that the problem of reducing the number of rats on shore merited the special consideration of Sanitary Authorities of seaports and seaport towns throughout the world, and that if the rat-proofing of ships really make it easier for ships to obtain exemption from fumigation they believed that shipowners would co-operate and that world shipping would become less and less a breeding ground for rats (*see also* Ref. 5).

The possibilities of rat-proofing continued to receive attention in the United States and the publication of an article on the rat-proofing of vessels in the Public Health Reports for July 17, 1925, aroused such widespread interest, especially among shipbuilders and shipowners, that the article was translated subsequently into several languages. A second and larger edition was published in December 1926.

Writing in his Annual Report for 1927, Sir George Newman stated:

"Though rat-proofing on shore is now a recognized practice the same cannot be said in regard to the application of the principles of rat-proofing in ships. Yet this is a matter which merits the serious consideration of naval architects, shipbuilders and shipowners. There can be little doubt that when the new International Sanitary Convention comes into operation the rat-proof ships will be at a great advantage over others when the question of the issue of a deratization exemption certificate has to be decided. It is frequently difficult and expensive, and it may be impossible, to make existing buildings or ships fully rat-proof, though many improvements can be effected in this direction by practical attention to minor details. In new construction, however, whether of buildings or ships, the application of the principles of rat-proofing should be neither difficult nor expensive and will fully repay any additional cost incurred."

A few Port Medical Officers of Health took the greatest interest in rat-proofing—notably Dr. Maurice Williams of Southampton—and a certain amount of rat-proofing was done on British vessels such as those of the Cunard S.S. Company—but it is the tramp rather than the mail steamer that carries plague. A third edition [4] of the American Memorandum was published in 1931 which covered all phases of rat-proofing as applied to ships both new and old, and copies were sent to the Medical Officers of Health of the Ports approved for the issue of Deratization and Deratization Exemption certificates. A further Report on Rat-proofing of new ships was published in 1939.

The benefits claimed in the U.S.A. from rat-proofing are summarized in a paper published in their Public Health reports for December 24, 1943, and when visiting the Quarantine Station, New York, in August 1943, it was learnt that it had never been necessary to fumigate a single vessel for the destruction of rats which had been constructed and structurally maintained in accordance with the rat-proofing specifications of the United States Public Health Service.

In June 1944 the Ministry of War Transport issued a memorandum on the rat-proofing of new ships and there seems little doubt that more and more attention will be paid to this method of combating the menace of rat plague.

Whilst Port Health Authorities in this country probably now regard rat-plague and smallpox as public enemies No. 1, they have many other responsibilities and the International Agreement of Brussels¹, for securing the gratuitous treatment at seaports of seamen when suffering from venereal disease, which was ratified by this country in 1925, added another to the list.

The next great advance resulted from the International Sanitary Convention of 1926 which was signed by the representatives of 66 countries and subsequently ratified by 44. It provides for the immediate notification by Governments to other Governments and to the Office International d'Hygiène publique of cases of plague (including rodent plague), cholera, yellow fever, epidemic typhus and smallpox, the last two diseases now being included in an International Sanitary Convention for the first time. When the formal conference was held in Paris to consider the draft revisions which had been prepared by the Office International, delegates still had in mind the disastrous pandemic of influenza in 1918-19 but a proposal to include influenza among the diseases dealt with in the Convention was not accepted, though subsequently the severe outbreak of dengue which occurred in Greece and other Mediterranean Countries in 1928 led to the International Convention for Mutual Protection against Dengue Fever of 1934.

The Convention, however, settled the much-disputed question of the procedure to be followed for dealing with the rat population in ships and preventing the spread of plague. Briefly, all vessels of signatory countries, except those engaged in national coast-wise trade, must be inspected at regular intervals of six months, to ascertain whether there are on board more than a minimum of rats. Any vessel on which there is evidence that the rat population is in excess must be subjected to deratization and a "Certificate of Deratization" on an approved form must be issued by the competent Authority. If, on the other hand, there is little or no evidence of rats in any vessel at the time of inspection a "Certificate of Exemption from Deratization", likewise on an approved form, must be granted. These Certificates will be recognized in the ports of other countries which have ratified the Convention and, in the absence of the occurrence of special circumstances such as plague amongst the rats on board, will exempt vessels from further fumigation during the six months following the issue of the Certificate.

¹ This agreement, which was initiated by the British Delegate, Sir George Buchanan, in May 1920 was drawn up by the Permanent Committee of the Office International d'Hygiène publique and after circulation to Governments by the Belgian Government, was signed at Brussels on December 1, 1924.

Port Health Authorities generally adopted the word "PORTELTH" as their telegraphic address.

The meaning of the old visual signals was also changed and the flag signal "Q"—the yellow flag—no longer indicates that the vessel is in quarantine, but means: "My ship is healthy and I request free pratique!"

New arrangements were laid down for establishing "mooring-stations" where "infected" or "suspected" vessels can be detained and dealt with, it being made obligatory that one at least should be within the Docks. The Port Health Officer can, however, with the concurrence of the Customs, designate special "mooring-stations" and is thus able to arrange for a vessel being isolated and dealt with at her ordinary berth—as indeed is commonly done.

Provision was also made for the approval of suitable ports for the issue of International Deratization and Deratization Exemption Certificates and the approximate numbers of such certificates issued, during recent years, at the 24 "Approved Ports"¹ in England and Wales with the method of deratization employed, are shown in the following table:

APPROXIMATE NUMBER OF DERATIZATION AND DERATIZATION
EXEMPTION CERTIFICATES ISSUED DURING 1933-1945.

Year	HCN			HCN and sul-phur		Sal-for-kose	Trapping and poison-ing	Exemption		Total issued
	Li- quid	Zylon B	Other meths.	Sul-phur	sul-phur			No. issued	%	
1933	375	81	22	648	5	2	19	1152	4261	70
1934	357	96	30	615	2	5	25	1130	4526	80
1935	244	77	8	613	3	8	23	976	4442	82
1936	251	72	14	608	6	7	31	989	4584	82
1937	232	112	18	562	3	5	27	959	4774	83
1938	243	124	24	462	11	1	6	871	4467	84
1939	192	113	13	388	10	3	8	727	4168	85
1940	164	99	31	351	14	3	18	680	3735	85
1941	191	135	20	311	10	1	11	679	2334	77
1942	282	248	8	138	26	—	12	714	1645	70
1943	434	273	8	66	21	—	17	819	1486	65
1944	527	304	5	60	7	—	13	916	1407	61
1945	669	354	45	40	20	—	26	1154	2035	65

With improvements in methods of fumigation, Port Health Authorities are finding that they are able to fumigate vessels while loaded with a reasonable prospect of destroying most of the rats on board, though this depends to a great extent on the nature of the cargo and its stowage in the holds. Many Authorities do not hesitate to fumigate before unloading if they fear that a ship may present a risk of the transfer of plague-infected rats ashore. In such cases the Quarantine Commission of the Paris Office expressed the view (in 1934) that only one of the fumigations should be at the charge of the ship, any subsequent fumigation being a charge on the port. This practice of repeated fumigations was not envisaged in the International Sanitary Convention of 1926 and its regularization will necessitate an amendment to the text of article 25—which is under consideration. In Great Britain "Bills of Health" have not been required for many years, but it is of interest to note that two parallel international agreements for the abolition of the Bill of Health and of the Consular visa thereon were drawn up by the Office International in 1934. It is quite anomalous that, though aeroplanes are not required to carry Bills of Health, some countries still demand them from the comparatively slow-moving ship. Under the International Sanitary Convention of 1944, however, Bills of Health and Consular visas are to be abolished "as soon as the conditions of hostilities permit the establishment of effective epidemiological communications".

Only a few other advances in Port Health Administration can be listed. In order that smallpox contacts proceeding abroad (before the incubation period of the disease has elapsed) might be kept under surveillance, the Ministry issued a circular (No. 1021) in 1929 asking that the requisite information in such cases should be furnished to the Ministry, who would then notify the appropriate Public Health Authority abroad. Similarly, a circular (No. 1171) was addressed to Port and Riparian Sanitary Authorities in 1931 regularizing the practice which was growing up of communicating any essential information, in regard to "infected" or "suspected" ships, by the port of arrival to the next port of call.

Arrangements were also made with Shipping Companies, the French Administration and our Consul-General at Marseilles for facilitating surveillance in this country of any contacts who land from vessels calling at Marseilles and proceed overland to one of the Channel Ports.

Under the International Sanitary Convention of 1926, the signatory countries agreed to keep one another informed, through the Office International, of the measures taken

¹ Barrow-in-Furness; Barry; Blyth; Bristol; Cardiff; Dover; Falmouth; Fowey; Grimsby; Hartlepool; Hull; Immingham; Liverpool; London; Manchester; Middlesbrough; Newport; Plymouth; Southampton; Sunderland; Swansea; Tyne; Weymouth; Workington; and the three naval ports: Chatham, Devonport and Portsmouth.

Following the consideration of this report the Office International issued provisional standards for the fumigation of vessels, and in 1931 the Ministry of Health issued a circular (No. 1194) to Port and Riparian Sanitary Authorities on Plague Preventive Measures. This circular emphasized the need for being constantly on the watch, for continuously applying measures for rat destruction and the elimination of harbourage and for Port Health Authorities keeping themselves regularly informed of the condition of the rats in the ports by frequent and systematic examination.

In this connexion the rat-flea survey carried out in the Port of Cardiff and described in Dr. Greenwood Wilson's Annual Report for 1934 is of particular interest.

The prevention of the landing of rats from a vessel known or suspected to be infected with rodent plague is one of the most serious problems with which Port Health Authorities are faced. The use of rat-guards was raised at the Office International d'Hygiène publique who, after considering the replies to a questionnaire sent to the various countries participating in the Office, concluded that:

(1) Rat-guards are only effective if they are suitably constructed, and if certain specific conditions are observed in regard to their application. In practice, the strict observance of these conditions presents so many difficulties that the Commission can only competently recommend the use of rat-guards if there is a real danger of the introduction of rat plague, which justifies the necessity for taking all possible measures for preventing the passage of rats.

(2) At present it is hardly possible to recommend the adoption of a uniform standard type of rat-guard, but certain principles, in regard to their construction, should be kept in view.

The Commission also suggested that further experiments should be made with the electrical type of guard and these were carried out at Bristol, Hull and Liverpool under the auspices of the Association of Port Sanitary Authorities, but in the report presented by Dr. Frazer, the conclusions were that the electrical type of rat-guard was not suitable for use at the ports in this country.

The recent appearance of human psittacosis led the permanent Committee of the Office International d'Hygiène publique to consider in 1930 the question of harmonizing the action taken by different countries to prevent the importation of parrots and the Parrots (Prohibition of Import) Regulations 1930 added a new responsibility to Port Medical Officers of Health.

To return to the story, the International Sanitary Convention of 1926 was finally implemented by the Port Sanitary Regulations of 1933, which came into force on May 1 of that year. Similar Regulations, which came into operation on the same date, were also issued by the Department of Health for Scotland and the Ministry of Home Affairs for Northern Ireland. Only a few modifications were necessary when the International Sanitary Convention of 1944 was implemented and as the Regulations are still in force—and indeed have well stood the test of time—only the salient points need be mentioned.

The aim of the regulations, which are partly administered by the Customs, was to give further effect to the obligations assumed under the 1926 Convention and to consolidate in one code the various then existing Regulations—such as the several general and special Cholera, Yellow Fever and Plague Regulations of 1907, the Port Sanitary Authorities (Infectious Diseases) Regulations, 1920, and the Public Health (Deratization of Ships) Regulations, 1929—which were revoked.

They provide for wireless messages from incoming vessels from foreign, the obligation of hoist signals¹ indicating the state of health on board (which the Master must ascertain before arrival) and the obligation on the Master to make a written Declaration of Health (which must be countersigned by the Ship's Surgeon, if one is carried).

With the advances made in the use of wireless after the 1914-18 war, radio messages were being more and more utilized as a means of communication between incoming vessels and the shore and the system introduced at Plymouth proved so successful that in the new Regulations, powers were given to the Minister to designate ports to which approaching ships (if fitted with suitable transmitting apparatus) must send a wireless message if there were infectious disease on board. To simplify the sending of the messages

¹ *International Code of Signals*.—Codes of signals for the use of mariners have been published in various countries since the beginning of the 19th Century. The best known is Captain Marryat's, which was published in 1817 and was probably the first international code. Various revisions were made and during the 1914-18 war the code drawn up in 1897 was in use, but broke down under war conditions. After the war, revision was undertaken at the suggestion of the British Government, first by the International Radiotelegraphic Conference at Washington in 1927 and later completed, at the request of this Conference, by the British Government with representatives of each of the governments concerned in 1931. The new code was compiled in two volumes, one for use by radiotelegraphy and the other by visual signalling: the British Edition being published in 1932. The code for radio signalling contains a complete medical section and a code for accelerating the granting of pratique which were inserted with the assistance and by the advice of the Office International d'Hygiène publique. Another feature of the new code is the introduction of words and phrases applicable to aircraft. Nautical and technical expressions have been adjusted in the seven editorial languages so that the use of the code will facilitate the exchange of correct and concise information between people not speaking the same language.

The progress of aviation, however, since the Wright Brothers made their first flight in 1903 and Bleriot flew the Channel in 1909, created new problems. An International Convention relating to the Regulation of Aerial Navigation was drawn up in 1919 the year the Atlantic was first flown by Alcock and Brown. Gradually it was recognized that the very speed of air traffic and the opening up of new air routes between country and country might produce special dangers of their own. This was notably the case with the establishment of regular air communications between countries in which yellow fever might exist and those countries which, though they have never known the infection of yellow fever, contain both susceptible populations and the species of mosquito by which the infection is carried from man to man. As a result the Office International d'Hygiène publique in 1930 drafted an International Sanitary Convention for Aerial Navigation which was so framed as to take full account of the special conditions of aircraft and of the circumstances in which they might be more, or less, likely than are ships to convey infection from country to country. The final text was opened for signature at the Hague in April 1933, but this convention has not been as widely accepted as the "Maritime" Convention of 1926. It was only signed by 23 countries, of whom 16 subsequently ratified but Bolivia, Brazil, Chile, Irak, the Soudan, Southern Rhodesia and a number of British Colonies and Protectorates afterwards adhered.

Briefly the Convention, which applies only to aircraft which pass from one territory to another, lays down the measures which may be taken for the control of infectious diseases introduced by aircraft and those which in cases of necessity must be taken to prevent the exportation of such diseases. Three classes of aerodromes are defined, viz:

- (i) Customs (or authorized) aerodromes.
- (ii) Sanitary aerodromes—which are Customs aerodromes properly organized, staffed and equipped, and
- (iii) Anti-amaryl aerodromes (in yellow fever areas) where mosquito-proof dwellings must be provided and persons can be subjected to observation for six days (to cover the incubation period of yellow fever). Other special precautions must also be enforced against mosquitoes.

When the Convention came into force there were 11 Customs aerodromes for the use of land-planes, four for sea-planes and one for the use of airships. These came under medical control by the Local Authority as legislation was then necessary before Regulations to implement the Convention could be finally drafted.

The Public Health (Aircraft) Regulations came into force on July 1, 1938, and are applicable to all aerodromes or places approved by the Commissioners of Customs for the landing or departure of foreign-going land-planes or sea-planes.

Twenty-four aerodromes were then approved as "Customs" aerodromes. Four of these, i.e. Doncaster, London (Croydon), London (Heston) and Southampton Water were designated by the Minister as Sanitary Aerodromes and the Office International d'Hygiène publique was duly informed in accordance with the terms of the International Sanitary Convention for Aerial Navigation.

The object of the Regulations was to prevent the introduction of infectious disease into the country by air-borne traffic which was rapidly increasing. They are administered (i) by Port Health Authorities, if the aerodromes or places for the landing of aircraft are within their district; (ii) by the local authority, including a county council, that maintains an aerodrome; and (iii) in respect to other aerodromes by the local authority of the district in which the aerodrome is situated. No grant has been payable but the cost of the medical inspection of aliens is met by the Exchequer.

When the Regulations came into force, the bulk of the traffic was dealt with at Croydon and Heston, whilst the long distance sea-planes of the old Imperial Airways used the Marine Airport at Southampton. The landing there of a doubtful case of cholera from India in August 1938, led Dr. Maurice Williams to introduce a simple form of "declaration of health" which materially assisted the arrangements for the surveillance of travellers arriving by air from countries where the more dangerous infectious diseases were present. Incidentally, about the same time, American Authorities introduced a "declaration of origin" from passengers coming from an area infected with yellow fever in the form of a statement of their movements during the six days previous to landing. When the International Sanitary Convention for Aerial Navigation of 1944 was drawn up these two forms were amalgamated into the Personal Declaration of Origin and Health form which, under this Convention, is demanded from passengers arriving on aircraft.

With the increase of air traffic, the Office International had many thorny problems to solve, perhaps one of the most important being the destruction of disease-carrying mosquitoes on aircraft. Whilst the Ministry collaborated with the old Imperial Airways in much of the pioneer work on the disinsectization of aircraft, there has been no need for any such general measures to be imposed on aeroplanes arriving in this country.

to ensure the application of the Convention, one result being that in 1930, the "Office" published the 1st edition of the International Quarantine Directory. A second edition containing information (up to April 1933) from one hundred Countries, Colonies or Protectorates, was published in 1934 and a Supplement was issued in 1937.

Port Sanitary Authorities have responsibilities beyond combating infectious disease on incoming vessels. Two incidents seem of sufficient interest to serve as examples, viz.: The case of anthrax in a London dock labourer, mentioned in Dr. Reece's Presidential Address; which was the first occasion when the infection was traced to Indian bone meal and the case of the S.S. "Jean L.D." This vessel arrived in the Port of London from South Africa in October 1937, and 32 of the original crew of 34 subsequently suffered from an obscure form of paralysis. The investigation showed that the condition was tri-orthocresyl phosphate poisoning—the so-called "ginger" or "jake" paralysis—due to partaking of contaminated salad oil [6].

As the Local Health Authority, Port Sanitary Authorities have responsibilities in regard to nuisances on ships lying within their jurisdiction. It is not surprising, therefore, that the hygiene of crew spaces has been a matter of particular interest to Port Medical Officers of Health and that some have forcibly expressed their views [7-12].

As far back as 1911 the congress of the Royal Sanitary Institute urged a thorough revision of the requirements in respect of the living quarters for officers and men of all new vessels and the Association of Port Sanitary Authorities made detailed recommendations in 1922 and again in 1935. It is therefore particularly satisfactory to record that in 1937 the Board of Trade issued new Instructions as to the survey of Masters and Crew spaces, based on more modern standards, which have gone a long way to remedy in new ships the old defects. Whilst nuisances on ships are usually dealt with by the officers of the Port Sanitary Authority, defects of construction and structural alterations are matters for the Board of Trade surveyors, the relative responsibilities being indicated in a circular (No. 1670) issued by the Minister in 1938 when forwarding copies of the revised Board of Trade instructions.

With the outbreak of the World War in 1939, new responsibilities devolved on Port Medical Officers of Health in connexion with Civil Defence. Crowds of refugees arrived and ports such as Dover and Harwich were taken over by the Admiralty for naval purposes, and traffic from many ports was diverted owing to enemy action and the introduction of the convoy system. Owing to the war, vessels had to change their routes and an increasing number of cases of malaria began to occur on arriving vessels. More and more ships on the way home were calling at Freetown and other West African ports, where malaria was being contracted.

Port Medical Officers of Health were circulated and asked to keep the possibility of malaria constantly in mind when examining sick persons on ships arriving from foreign and specially those which had called at West-African ports and to forward to the Ministry particulars of all vessels on which malaria had occurred during the voyage.

A summary of the returns received to the end of 1944 is given in the following table:

CASES OF MALARIA ON SHIPS.

Year	No. of ships	Cases reported	Deaths reported
1940 (last six months)	152	354	11
1941	243	756	14
1942	152	859	12
1943	143	845	8
1944	166	780	9
Totals	826	3,504	54

As the war progressed much strain was thrown on many ports whose normal staff had already been depleted by the call to the Armed Forces but the history of the War Years yet remains to be written.

One reform, however, which was long overdue, was finally accomplished. To meet the views of the Association of Port Sanitary Authorities, the designation was changed to Port Health Authorities by the Public Health Act of 1936, but there were difficulties then in effecting the consequential amendment in the title "Port Sanitary Regulation". When it became necessary to give effect to the provisions of the International Sanitary Convention of 1944, the anomaly was corrected in the Port Health Amendment Regulation of 1945, and our sea ports at last have Port Health Authorities and Port Health Regulations.

II. AIR TRAFFIC

In reviewing the progress of Port Health Administration much attention has of necessity been devoted to maritime traffic.

The progress of aviation, however, since the Wright Brothers made their first flight in 1903 and Bleriot flew the Channel in 1909, created new problems. An International Convention relating to the Regulation of Aerial Navigation was drawn up in 1919 the year the Atlantic was first flown by Alcock and Brown. Gradually it was recognized that the very speed of air traffic and the opening up of new air routes between country and country might produce special dangers of their own. This was notably the case with the establishment of regular air communications between countries in which yellow fever might exist and those countries which, though they have never known the infection of yellow fever, contain both susceptible populations and the species of mosquito by which the infection is carried from man to man. As a result the Office International d'Hygiène publique in 1930 drafted an International Sanitary Convention for Aerial Navigation which was so framed as to take full account of the special conditions of aircraft and of the circumstances in which they might be more, or less, likely than are ships to convey infection from country to country. The final text was opened for signature at the Hague in April 1933, but this convention has not been as widely accepted as the "Maritime" Convention of 1926. It was only signed by 23 countries, of whom 16 subsequently ratified but Bolivia, Brazil, Chile, Irak, the Soudan, Southern Rhodesia and a number of British Colonies and Protectorates afterwards adhered.

Briefly the Convention, which applies only to aircraft which pass from one territory to another, lays down the measures which may be taken for the control of infectious diseases introduced by aircraft and those which in cases of necessity must be taken to prevent the exportation of such diseases. Three classes of aerodromes are defined, viz:

- (i) Customs (or authorized) aerodromes.
- (ii) Sanitary aerodromes—which are Customs aerodromes properly organized, staffed and equipped, and
- (iii) Anti-amaryl aerodromes (in yellow fever areas) where mosquito-proof dwellings must be provided and persons can be subjected to observation for six days (to cover the incubation period of yellow fever). Other special precautions must also be enforced against mosquitoes.

When the Convention came into force there were 11 Customs aerodromes for the use of land-planes, four for sea-planes and one for the use of airships. These came under medical control by the Local Authority as legislation was then necessary before Regulations to implement the Convention could be finally drafted.

The Public Health (Aircraft) Regulations came into force on July 1, 1938, and are applicable to all aerodromes or places approved by the Commissioners of Customs for the landing or departure of foreign-going land-planes or sea-planes.

Twenty-four aerodromes were then approved as "Customs" aerodromes. Four of these, i.e. Doncaster, London (Croydon), London (Heston) and Southampton Water were designated by the Minister as Sanitary Aerodromes and the Office International d'Hygiène publique was duly informed in accordance with the terms of the International Sanitary Convention for Aerial Navigation.

The object of the Regulations was to prevent the introduction of infectious disease into the country by air-borne traffic which was rapidly increasing. They are administered (i) by Port Health Authorities, if the aerodromes or places for the landing of aircraft are within their district; (ii) by the local authority, including a county council, that maintains an aerodrome; and (iii) in respect to other aerodromes by the local authority of the district in which the aerodrome is situated. No grant has been payable but the cost of the medical inspection of aliens is met by the Exchequer.

When the Regulations came into force, the bulk of the traffic was dealt with at Croydon and Heston, whilst the long distance sea-planes of the old Imperial Airways used the Marine Airport at Southampton. The landing there of a doubtful case of cholera from India in August 1938, led Dr. Maurice Williams to introduce a simple form of "declaration of health" which materially assisted the arrangements for the surveillance of travellers arriving by air from countries where the more dangerous infectious diseases were present. Incidentally, about the same time, American Authorities introduced a "declaration of origin" from passengers coming from an area infected with yellow fever in the form of a statement of their movements during the six days previous to landing. When the International Sanitary Convention for Aerial Navigation of 1944 was drawn up these two forms were amalgamated into the Personal Declaration of Origin and Health form which, under this Convention, is demanded from passengers arriving on aircraft.

With the increase of air traffic, the Office International had many thorny problems to solve, perhaps one of the most important being the destruction of disease-carrying mosquitoes on aircraft. Whilst the Ministry collaborated with the old Imperial Airways in much of the pioneer work on the disinsectization of aircraft, there has been no need for any such general measures to be imposed on aeroplanes arriving in this country.

to ensure the application of the Convention, one result being that in 1930, the "Office" published the 1st edition of the International Quarantine Directory. A second edition containing information (up to April 1933) from one hundred Countries, Colonies or Protectorates, was published in 1934 and a Supplement was issued in 1937.

Port Sanitary Authorities have responsibilities beyond combating infectious disease on incoming vessels. Two incidents seem of sufficient interest to serve as examples, viz.: The case of anthrax in a London dock labourer, mentioned in Dr. Reece's Presidential Address, which was the first occasion when the infection was traced to Indian bone meal and the case of the S.S. "Jean L.D." This vessel arrived in the Port of London from South Africa in October 1937, and 32 of the original crew of 34 subsequently suffered from an obscure form of paralysis. The investigation showed that the condition was tri-orthocresyl phosphate poisoning—the so-called "ginger" or "jake" paralysis—due to partaking of contaminated salad oil [6].

As the Local Health Authority, Port Sanitary Authorities have responsibilities in regard to nuisances on ships lying within their jurisdiction. It is not surprising, therefore, that the hygiene of crew spaces has been a matter of particular interest to Port Medical Officers of Health and that some have forcibly expressed their views [7-12].

As far back as 1911 the congress of the Royal Sanitary Institute urged a thorough revision of the requirements in respect of the living quarters for officers and men of all new vessels and the Association of Port Sanitary Authorities made detailed recommendations in 1922 and again in 1935. It is therefore particularly satisfactory to record that in 1937 the Board of Trade issued new Instructions as to the survey of Masters and Crew spaces, based on more modern standards, which have gone a long way to remedy in new ships the old defects. Whilst nuisances on ships are usually dealt with by the officers of the Port Sanitary Authority, defects of construction and structural alterations are matters for the Board of Trade surveyors, the relative responsibilities being indicated in a circular (No. 1670) issued by the Minister in 1938 when forwarding copies of the revised Board of Trade instructions.

With the outbreak of the World War in 1939, new responsibilities devolved on Port Medical Officers of Health in connexion with Civil Defence. Owing to the war, vessels had to change their routes and an increasing number of cases of malaria began to occur on arriving vessels. More and more ships on the way home were calling at Freetown and other West African ports, where malaria was being contracted.

Port Medical Officers of Health were circulated and asked to keep the possibility of malaria constantly in mind when examining sick persons on ships arriving from foreign and specially those which had called at West-African ports and to forward to the Ministry particulars of all vessels on which malaria had occurred during the voyage.

A summary of the returns received to the end of 1944 is given in the following table:

CASES OF MALARIA ON SHIPS.

Year	No. of ships	Cases reported	Deaths reported
1940 (last six months)	132	354	11
1941	243	756	14
1942	152	859	12
1943	143	845	8
1944	156	780	9
Totals	826	3,594	54

As the war progressed much strain was thrown on many ports whose normal staff had already been depleted by the call to the Armed Forces but the history of the War Years yet remains to be written.

One reform, however, which was long overdue, was finally accomplished. To meet the views of the Association of Port Sanitary Authorities, the designation was changed to Port Health Authorities by the Public Health Act of 1936, but there were difficulties then in effecting the consequential amendment in the title "Port Sanitary Regulation". When it became necessary to give effect to the provisions of the International Sanitary Convention of 1944, the anomaly was corrected in the Port Health Amendment Regulation of 1945, and our sea ports at last have Port Health Authorities and Port Health Regulations.

II. AIR TRAFFIC

In reviewing the progress of Port Health Administration much attention has of necessity been devoted to maritime traffic.

JOINT DISCUSSION No. 3

Section of Neurology with the Section of Radiology

Chairman—J. PURDON MARTIN, M.D., F.R.C.P.

(President of the Section of Neurology)

[February 15, 1946]

RADIATION TREATMENT OF CEREBRAL TUMOURS

Dr. R. McWhirter: The following investigation into the radiosensitivity of brain tumours was undertaken in association with the Department of Surgical Neurology and I should like at the outset to acknowledge its most helpful co-operation in the investigation and in the preparation of this Address.

Ten years ago our knowledge of the radiosensitivity of the different forms of brain tumour was restricted. Accordingly when this investigation was begun in 1936 it was decided that wherever possible the exact histological nature of the tumour to be irradiated would be determined and that all cases would be carefully followed up.

Cases selected for consideration.—All cases histologically proven and treated by radiotherapy as part of the first planned method of treatment during the period 1936 to 1944 have been included.

In a number of cases the X-ray treatment was incomplete either because of deterioration in the patient's general condition or because the tumour was obviously radio-insensitive. All such cases have, however, been included in the following tables, for their omission would give an erroneous impression of the value of radiotherapy.

All deaths have been assumed to be due to the tumour. Of the total 115 cases 4 have not been fully traced, making the percentage of cases lost sight of 3.5%.

Spongiblastoma polare has been included with the astrocytomas and the astroblastoma with the glioblastomas.

TABLE I.—ALL HISTOLOGICALLY PROVEN BRAIN TUMOURS, 1936-1944.

	Total	No. treated by X-rays
Astrocytomas	61	7
Ependymomas	8	4
Oligodendrogliomas	5	5
Meningiomas	74	33
Hamangioblastomas	15	10
Neuro-epitheliomas	2	2
Medulloblastomas	19	13
Ependymoblastomas	17	11
Malignant choroidal papillomas	6	3
Pinealoblastomas	11	2
Glioblastomas	106	25
Total	324	115

Following consideration of the above group of tumours, a brief comment will be made on the tumours of the pituitary region and on spinal tumours.

Method of treatment.—The extent of the surgical treatment has varied. In 5 out of the 115 cases the tumour was apparently completely removed, but because complete removal could not be guaranteed radiotherapy was given later. In the remainder only a partial removal of the tumour was undertaken or only sufficient tissue was removed for histological examination.

In the majority of cases a decompression was carried out so that the tumour could be accurately localized and its extent determined. Where there was interference with the fluid circulation, sufficient tumour tissue was removed to overcome this. When cysts were present these were opened to diminish the bulk of the tumour. Decompression also permitted of inspection of the gross appearance of the tumour and, as will be shown later, this is of considerable importance in the selection of the meningiomas likely to be suitable for radiotherapy.

From the data of clinical neurology, air ventriculography and operation findings, the position and the extent of the tumours were assumed and were marked on anterior and lateral radiographs and the patient sent for radiotherapy.

The X-ray treatment has naturally undergone some modification over the period but in general patients were treated by X-rays generated at 250 kV. and filtered by a Thoracufilter. Two directly opposed fields centred over the tumour were used and each field was treated every day. A minimum tumour dose of 4,500 r in four weeks was planned but, as already indicated, this dose level was not reached in a number of cases.

Following the outbreak of the war, ordinary civilian air traffic gradually decreased and aerodromes came more and more under R.A.F. control. The difficulties of proper surveillance of passengers arriving by air also increased and arising out of a suggestion by Dr. Chesney—the Port M.O.H. of Poole—Dr. Goodman and Mr. Dark of the Ministry of Health drew up a card which is now handed to each passenger from abroad when he arrives, on which is printed a notice in English and French warning him that while abroad he may have been in contact, without knowing it, with some dangerous infectious disease and urging him at once to consult a doctor and to show him the card should he fall ill within twenty-one days of arrival. On the reverse side of the card the attention of the doctor is drawn to the fact that his patient has been abroad and he is asked, if infectious disease is found or suspected, at once to notify the Medical Officer of Health and inform him of the date and airport (which is given on the card) of the patient's arrival. These particulars will help in locating other passengers who travelled on the same plane and the taking of other precautions.

As smallpox is now the chief danger to be apprehended the original card is being revised to stress this disease and incidentally the Services have introduced a "warning-card" which is handed to their personnel who have travelled on ships on which smallpox has occurred during the voyage.

To what extent this system will obviate the necessity of placing unprotected travellers from infected areas under surveillance it is difficult to judge, but the underlying idea of getting each passenger to carry out his own surveillance is being given an extended trial.

III. THE UNRRA CONVENTIONS

Towards the end of 1943, when the United Nations Relief and Rehabilitation Administration was formed, one of the main aims was to provide aid in the prevention of pestilence. Fears were then expressed of the danger of epidemics in the liberated countries and as Paris was then in enemy hands and no help could be obtained from the Office International d'Hygiène publique, an expert Commission on Quarantine was set up, the terms of reference being to consider the scope of the existing International Sanitary Conventions and to draft any necessary amendments of an emergency nature taking into account the progress of medical knowledge since the 1926 and 1933 Conventions were prepared—particularly in regard to yellow fever and the increasing speed of air travel. As a result, two new International Sanitary Conventions came into force on January 15, 1945 (UNRRA becoming the international body responsible for administering them for the time being), viz.: the International (Maritime) Sanitary Convention of 1944 amending the International Sanitary Convention of 1926, which has been implemented by the Port Health Amendment Regulations of 1945, and the International (Aerial) Sanitary Convention of 1944 amending the International Sanitary Convention for Aerial Navigation of 1933. This latter Convention has not yet been fully implemented as legislation is awaited in connexion with the recently formed Ministry of Civil Aviation. Particulars of these Conventions have, however, already been communicated to this Section [13].

Before concluding this outline of Port Health Administration, during the period which practically coincides with the life of this Section of the Royal Society of Medicine, I should be lacking in appreciation if I did not pay my tribute to the work of Port Medical Officers and their staffs. To have given a fuller account of the many duties they now carry out would be impossible in a single paper. The work calls for initiative and quick decision. To wait on a dirty night, in a tossing launch, for the ship which may be delayed, to climb the rope ladder and then make the right diagnosis in the minimum of time requires pluck, character and skill. Wireless telephony should gradually lessen the difficulties of the boarding officer but that so few mistakes have been made in the past twenty-five years is a greater tribute to the efficiency of the Port Health Service than any I could voice and one which would delight the heart of Richard Reece were he with us to-day.

degree of accuracy the radiosensitive tumours from the radio-insensitive tumours and has made the following observations:

"Meningiomas with extensive hyperostosis are sensitive. Meningiomas, where the blood supply is mainly dural, are insensitive. Those with a cerebral blood supply are sensitive (excluding the intraventricular types). The meningiomas of multilobular form with a smooth firm oedematous cortex and soft pale interior within the lobules, with the larger blood-vessels on the surface and in the septa between the lobules are sensitive. The firm solid tumours with a granular surface and with vessels evenly distributed throughout a tough homogeneous substance are insensitive. Most of the meningiomas *en plaque*—both the soft and the pale hard avascular types—are sensitive.

"In a group of 82 meningiomas 22 cases (or 27%) were proved to be radiosensitive, 10 (or 12%) were proved to be radio-insensitive. A further 13 (or 16%) have been assumed to be radiosensitive. This makes a total of 43% of the meningiomas suitable for treatment by X-ray therapy."

(3) *The radiosensitive metastasizing tumours:*

TABLE IV.

		Years after treatment	Exposed to risk	qx	Survival rate %
Medulloblastomas ...	13	0	29	0.2069	100
Ependymoblastomas ...	11	1	21	0.2857	79.31
Malignant choroidal papillomas	3	2	19	0.5000	56.65
Pinealoblastomas ...	2	3	5	0	28.32
		4	4	0.5000	28.32
Total admissions	29	5	—	—	14.16

The five-year survival rate in this group is 14%.

All the tumours in this group are highly radiosensitive and little difficulty was experienced in the destruction of the main primary tumour mass. Failure to cure the patient was due to the fact that these tumours have a marked tendency to metastasize to other parts of the cerebrospinal axis, and, in particular, to the basal cisterns and to the spinal canal.

The method of treatment in this group has now been changed and localized treatment has been replaced by extensive fields arranged so as to include the whole of the cerebrospinal axis. The best method of treating this large area is still under investigation and has not yet been finally determined.

(4) *The ? radiosensitive tumours:*

TABLE V.

		Years after treatment	Exposed to risk	qx	Survival rate %
Glioblastomas ...	25	0	25	0.4400	100
		1	14	1.0000	56.00
Total admissions	25	2	0	—	0
		3	0	—	—
		4	0	—	—
		5	—	—	—

The glioblastomas have been placed in a separate category. Thus, while at present the application of X-radiation to glioblastomas is of doubtful value, there is evidence that some of these tumours are not entirely unresponsive, and we propose to keep an open mind regarding future possibilities as radiotherapeutic technique may improve in tumour lethal potency and neoplastic selectivity.

All the histologically proven tumours:

TABLE VI.

		Years after treatment	Exposed to risk	qx	Survival rate %
(1) Radio-insensitive tumours ...	23	0	114.5	0.2009	100.0
(2) Radiosensitive non-metastasizing tumours ...	34	1	81	0.3457	79.91
		2	42	0.2143	52.20
(3) Radiosensitive metastasizing tumours ...	29	3	26.5	0.0755	41.08
		4	14	0.2357	37.93
(4) ? radiosensitive tumours ...	25	5	—	—	27.13
Total admissions	115				

The five-year survival rate of all cases is 27%.

With the increased knowledge now available cases will be more carefully selected for X-ray treatment, and, if a suitable method of treatment can finally be elaborated for the radiosensitive metastasizing tumours (Group 3) the results in the future will probably show considerable improvement.

Pituitary tumours.—Only a brief comment will be made for the main object of this paper has been to present the findings in the group of tumours already discussed.

Chromophobe adenomas are no longer treated by radiotherapy for no conclusive evidence of their response to treatment has been obtained. In assessing the value of radiotherapy it must be borne in mind that spontaneous arrest of growth for indefinite periods and even spontaneous retrogression are in fact not uncommon.

The eosinophil tumours are suitable for treatment by X-ray therapy. In the majority of cases the rate of advancement of the acromegaly is slowed down and in some cases definite improvement may be obtained. Further, the bulk of tumour may significantly

Assessment of the effect of radiotherapy.—It is always difficult to assess accurately the precise effect of radiotherapy on any tumour which cannot be directly inspected during the whole course of treatment and subsequently. The following observations are based mainly on the clinical assessment of the size of the tumour as a space-occupying mass, in terms of its effect on cerebral function and in terms of brain plus tumour volume as judged from fullness or recession at cranial defects. In some cases still more accurate assessment has been possible. Further operations have been undertaken in a number of cases (in particular in the meningiomas proved to be insensitive) and the gross appearances and the histological findings after treatment have been compared with those of the original operation. A post-mortem examination has been obtained in a number of cases. In others X-ray examination has provided useful information. Thus subsequent ventriculography may show the absence or persistence of the mass. In one case where fine specks of calcification were present throughout the tumour it was possible to follow the shrinkage of the tumour during treatment to the final stage where the calcification was reduced to a thin plaque.

From the above observation it has been possible to classify the brain tumours into four main groups:

(1) *The radio-insensitive tumours:*

			TABLE II.	Exposed	qx*	Survival
			Years after treatment	to risk		rate %
Astrocytomas	7	0	22.5	0.1778	100
Ependymomas	4	1	16	0.4375	82.22

*qx is the probability or chance of dying in any one year.

It will be seen from the table that 26% of the patients in this group are alive at the end of five years.

The astrocytomas, the ependymomas and the oligodendrogliomas are all slowly growing tumours and patients with these tumours may survive for more than five years with no treatment at all. In assessing the value of radiotherapy, therefore, the survival rate is of little value. The survival rate in the above group did not differ materially from cases receiving no radiotherapy. There was no clinical proof that the tumour mass had diminished in size and where subsequent operation was carried out the tumour was unaltered.

The meningiomas will be considered more fully in the next section where it will be shown that from the radiotherapeutic point of view there are two types of meningioma—one radiosensitive and the other radio-insensitive. The radio-insensitive tumours are, of course, included above. When the tumour was found to be radio-insensitive subsequent operation was performed in a number of cases and the tumour removed. The absence of radiation effect upon its bulk and its component cells was then verified.

From what has been said it will be appreciated that the five-year survival rate of 26% is due to the naturally slow growth of the first three tumours and to the mechanical gains from partial tumour removals and from decompressive effects. It is possible that while radiotherapy did not cause diminution in the tumour bulk it may have slowed down the rate of growth of these tumours. The subsequent total surgical removal of some of the meningiomas has also influenced the five-year survival rate.

(2) *The radiosensitive non-metastasizing tumours:*

			TABLE III.	Exposed	qx	Survival
			Years after treatment	to risk		rate %
Radiosensitive meningiomas	26		0	38	0.0526	100
Hæmangioblastomas ...	10		1	30	0.0333	94.74
Neuro-epitheliomas ...	2		2	23	0.0435	91.53
			3	15.5	0.0645	87.60
			4	8	0.2500	81.95
			5	—	—	61.49
Total admissions	38					

This group has given the best results and it will be seen that the five-year survival rate is 61%.

The radiosensitive meningiomas form the biggest group. That some meningiomas were radiosensitive was recognized as early as 1936 and it is of considerable interest to record that so far it has been impossible from histology alone to differentiate between the radiosensitive and the radio-insensitive meningiomas. The average duration of symptoms before treatment in the radiosensitive group is about two years and about five and a half years in the radio-insensitive group, but the figures for individual cases have too wide a variation to permit of the duration alone being used as a means of differentiating between the two types. From his clinical experience and from the gross anatomical appearances at the time of operation Mr. Dott can distinguish with a fair

degree of accuracy the radiosensitive tumours from the radio-insensitive tumours and has made the following observations:

"Meningiomas with extensive hyperostosis are sensitive. Meningiomas, where the blood supply is mainly dural, are insensitive. Those with a cerebral blood supply are sensitive (excluding the intraventricular types). The meningiomas of multilobular form with a smooth firm oedematous cortex and soft pale interior within the lobules, with the larger blood-vessels on the surface and in the septa between the lobules are sensitive. The firm solid tumours with a granular surface and with vessels evenly distributed throughout a tough homogeneous substance are insensitive. Most of the meningiomas *en plaque*—both the soft and the pale hard avascular types—are sensitive.

"In a group of 82 meningiomas 22 cases (or 27%) were proved to be radiosensitive, 10 (or 12%) were proved to be radio-insensitive. A further 13 (or 16%) have been assumed to be radiosensitive. This makes a total of 43% of the meningiomas suitable for treatment by X-ray therapy."

(3) The radiosensitive metastasizing tumours:

TABLE IV.					
		Years after treatment	Exposed to risk	qx	Survival rate %
Medulloblastomas ...	13	0	29	0.2009	100
Ependymoblastomas ...	11	1	21	0.2857	79.31
Malignant choroidal papillomas	3	2	10	0.5000	56.65
Pinealoblastomas ...	2	3	5	0	28.32
		4	4	0.5000	28.32
Total admissions	29	5	—	—	14.16

The five-year survival rate in this group is 14%.

All the tumours in this group are highly radiosensitive and little difficulty was experienced in the destruction of the main primary tumour mass. Failure to cure the patient was due to the fact that these tumours have a marked tendency to metastasize to other parts of the cerebrospinal axis, and, in particular, to the basal cisterns and to the spinal canal.

The method of treatment in this group has now been changed and localized treatment has been replaced by extensive fields arranged so as to include the whole of the cerebrospinal axis. The best method of treating this large area is still under investigation and has not yet been finally determined.

(4) The ? radiosensitive tumours:

TABLE V.					
		Years after treatment	Exposed to risk	qx	Survival rate %
Glioblastomas ...	25	0	25	0.4400	100
		1	14	1.0000	56.00
Total admissions	25	2	6	—	0
		3	0	—	—
		4	0	—	—
		5	—	—	—

The glioblastomas have been placed in a separate category. Thus, while at present the application of X-radiation to glioblastomas is of doubtful value, there is evidence that some of these tumours are not entirely unresponsive, and we propose to keep an open mind regarding future possibilities as radiotherapeutic technique may improve in tumour lethal potency and neoplastic selectivity.

All the histologically proven tumours:

TABLE VI.					
		Years after treatment	Exposed to risk	qx	Survival rate %
(1) Radio-insensitive tumours ...	23	0	114.5	0.2009	100.0
(2) Radiosensitive non-metastasizing tumours ...	34	1	81	0.3457	79.91
(3) Radiosensitive metastasizing tumours ...	29	2	42	0.2143	52.29
(4) ? radiosensitive tumours ...	25	3	26.5	0.0755	41.04
		4	14	0.2857	37.98
		5	—	—	27.13
Total admissions	115	—	—	—	—

The five-year survival rate of all cases is 27%.

With the increased knowledge now available cases will be more carefully selected for X-ray treatment, and, if a suitable method of treatment can finally be elaborated for the radiosensitive metastasizing tumours (Group 3) the results in the future will probably show considerable improvement.

Pituitary tumours.—Only a brief comment will be made for the main object of this paper has been to present the findings in the group of tumours already discussed.

Chromophobe adenomas are no longer treated by radiotherapy for no conclusive evidence of their response to treatment has been obtained. In assessing the value of radiotherapy it must be borne in mind that spontaneous arrest of growth for indefinite periods and even spontaneous retrogression are in fact not uncommon.

The eosinophil tumours are suitable for treatment by X-ray therapy. In the majority of cases the rate of advancement of the acromegaly is slowed down and in some cases definite improvement may be obtained. Further, the bulk of tumour may significantly

Assessment of the effect of radiotherapy.—It is always difficult to assess accurately the precise effect of radiotherapy on any tumour which cannot be directly inspected during the whole course of treatment and subsequently. The following observations are based mainly on the clinical assessment of the size of the tumour as a space-occupying mass, in terms of its effect on cerebral function and in terms of brain plus tumour volume as judged from fullness or recession at cranial defects. In some cases still more accurate assessment has been possible. Further operations have been undertaken in a number of cases (in particular in the meningiomas proved to be insensitive) and the gross appearances and the histological findings after treatment have been compared with those of the original operation. A post-mortem examination has been obtained in a number of cases. In others X-ray examination has provided useful information. Thus subsequent ventriculography may show the absence or persistence of the mass. In one case where fine specks of calcification were present throughout the tumour it was possible to follow the shrinkage of the tumour during treatment to the final stage where the calcification was reduced to a thin plaque.

From the above observation it has been possible to classify the brain tumours into four main groups:

(1) *The radio-insensitive tumours:*

				TABLE II.		
				Years after treatment	Exposed to risk	Survival rate %
Astrocytomas	7	0	22.5	0.1778
Ependymomas	4	1	16	0.4375
Oligodendrogliomas	5	2	9	0.3333
Radio-insensitive meningiomas	7	3	6	0.1667
				4	2	0
Total admissions	23			5	—	—

*qx is the probability or chance of dying in any one year.

It will be seen from the table that 26% of the patients in this group are alive at the end of five years.

The astrocytomas, the ependymomas and the oligodendrogliomas are all slowly growing tumours and patients with these tumours may survive for more than five years with no treatment at all. In assessing the value of radiotherapy, therefore, the survival rate is of little value. The survival rate in the above group did not differ materially from cases receiving no radiotherapy. There was no clinical proof that the tumour mass had diminished in size and where subsequent operation was carried out the tumour was unaltered.

The meningiomas will be considered more fully in the next section where it will be shown that from the radiotherapeutic point of view there are two types of meningioma—one radiosensitive and the other radio-insensitive. The radio-insensitive tumours are, of course, included above. When the tumour was found to be radio-insensitive subsequent operation was performed in a number of cases and the tumour removed. The absence of radiation effect upon its bulk and its component cells was then verified.

From what has been said it will be appreciated that the five-year survival rate of 26% is due to the naturally slow growth of the first three tumours and to the mechanical gains from partial tumour removals and from decompressive effects. It is possible that while radiotherapy did not cause diminution in the tumour bulk it may have slowed down the rate of growth of these tumours. The subsequent total surgical removal of some of the meningiomas has also influenced the five-year survival rate.

(2) *The radiosensitive non-metastasizing tumours:*

				TABLE III.		
				Years after treatment	Exposed to risk	Survival rate %
Radiosensitive meningiomas	26			0	38	0.0526
Hæmangioblastomas	...	10		1	30	0.0333

				3	15.5	0.0645
Total admissions	38			4	8	0.2500
				5	—	—

This group has given the best results and it will be seen that the five-year survival rate is 61%.

The radiosensitive meningiomas form the biggest group. That some meningiomas were radiosensitive was recognized as early as 1936 and it is of considerable interest to record that so far it has been impossible from histology alone to differentiate between the radiosensitive and the radio-insensitive meningiomas. The average duration of symptoms before treatment in the radiosensitive group is about two years and about five and a half years in the radio-insensitive group, but the figures for individual cases have too wide a variation to permit of the duration alone being used as a means of differentiating between the two types. From his clinical experience and from the gross anatomical appearances at the time of operation Mr. Dott can distinguish with a fair

symptoms for a very long time, and if a course of radiation treatment is given there is no way of saying what effect it has had on the tumour. We have one or two cases of oligodendroglioma which have not had a decompression but have been treated with radiation through the intact skull, and they have remained fairly well for periods of three or four years. We have also had some cases of astrocytoma of the basal ganglia which have had simple decompressions followed by radiation treatment with survival periods of three or four years. These tumours are, to some extent, radiosensitive and worth treating.

Three cases of meningiomata have been treated by radiation therapy, one in the cerebellopontine angle, one on the upper and posterior surface of the petrous bone, and one in both frontal regions, and only in the last case has there been any improvement. This was a very vascular tumour, with vascular channels in the skull the size of one's little finger, and the patient, a middle-aged woman, became repeatedly exsanguinated at repeated operations to expose and partially remove the tumour. Now after two years and one course of deep therapy, the decompression area is indrawn and she is free from symptoms. However, we have not done a ventriculogram to see whether, or how much, tumour remains.

Our results with the cerebellar medulloblastoma do not differ significantly from those previously published. Our best case looks like being that of a young adult who had a tumour of the upper vermis extending into the left cerebellar lobe completely removed in September 1942. It was thought at operation to be an ependymoma, but histological examination left no doubt that it was a characteristic medulloblastoma. He was thus given a course of deep therapy following operation, and to date there has been no sign of recurrence. One wonders whether we should not more often try to effect a wide removal of these tumours and follow this with a course of radiation treatment—although in those cases in which the floor of the fourth ventricle is involved, or in which there are already meningeal metastases, surgery probably has little to offer.

The cerebellar ependymoma, a tumour which usually grows in the lower part of the fourth ventricle, is often attached to the floor or to the calamus scriptorius, and presents as a mass in the cisterna magna. These are essentially benign tumours, but their situation usually means that complete removal is not possible without doing irreparable damage to the medulla. It has been the experience of most people, however, that a subtotal removal, leaving a fringe of attachment to the calamus will keep these patients free from symptoms for a number of years, if not permanently.

In November 1939 we admitted a little girl aged 7 with a short history of headache, vomiting, unsteadiness in walking, which symptoms confined her to bed within two or three weeks. On examination, there was no enlargement of the skull, intense papilloedema, nystagmus to both sides, ataxy of all four limbs, with in the lower limbs a considerable flaccid weakness and absence of tendon reflexes, sphincteric paralysis, and a good deal of pain in the back. Clinically this looked like a medulloblastoma with spinal metastases. A ventriculogram indicated a tumour in the lower part of the fourth ventricle and she was given a trial course of deep therapy. The result was immediate and dramatic, and was regarded as confirming the diagnosis. Within four or five weeks she had regained her normal health, and it was not possible to demonstrate any neurological abnormalities. She had a relapse about a year later, and again a course of treatment brought about this dramatic improvement. She finally died in a third relapse in December 1943, four years after the onset of symptoms, and at autopsy we found a characteristic ependymoma.

It may be a good idea to give a course of treatment as a routine in these cases.

Have we really any evidence that radiation treatment has an effect on brain tumours? I think anyone who has seen the response of a medulloblastoma to a course of X-ray therapy would say yes. But even with these tumours it is a prolongation of life and not a cure which we achieve. Are brain tumours ever cured by radiation? We have experience of one case in which the answer to that, too, is in the affirmative.

In April 1935 a young woman was admitted to the National Hospital, Queen Square, under the care of Dr. Critchley. She had been in good health until two months before admission when, after a mild attack of influenza, she began to complain of progressively severe headache and vomiting, and she had two epileptic attacks characterized by turning of the head and eyes to the left side, and convulsive movements of the left side of the face and left upper limb. After the second of these there was a progressive weakness of the left side of her body. On examination there was bilateral papilloedema, and a slight but definite weakness of the left limbs and face, with a corresponding alteration in the reflexes. X-rays of the skull were normal, but the spinal fluid pressure was elevated and the fluid contained an excess of protein. There was thus little doubt that there was an expanding lesion in the right frontal region, either a rapidly growing glioma or possibly an abscess. At operation Mr. Hugh Cairns found a subcortical glioma in the right frontal lobe. Sufficient of this was removed for histological examination and Dr. Greenfield demonstrated that it was a glioblastoma multiforme, of a malignant type. There was some improvement after operation, notably in the relief of headache and subsidence of papilloedema, but little alteration in the left-sided weakness. Four weeks after operation a course of radium treatment was given, 44,400 mg.-hrs. (100 mg. plaque) directed to the right frontal region.

decrease as evidenced by improvement in visual field defects and other signs of local pressure effects.

In Cushing's syndrome where the cause is a basophil pituitary tumour very striking results may be obtained. It always remains difficult, however, to identify those cases where the syndrome is actually due to a basophil pituitary tumour.

Craniopharyngeal carcinoma (pharyngeal endothelioma)—the invasive tumour of the base of the skull which appears to be a primitive type of carcinoma akin to branchial carcinoma is highly radiosensitive and good results have been obtained over a number of years of observation.

Spinal cord tumours.—The response is similar to that found in the cerebral tumours with the exception that the spinal cord meningiomas all appear to be radio-insensitive.

Mr. J. Pennybacker: The difficulties of assessing the value of radiation are greater in the case of brain tumours than with tumours in most other parts of the body. We cannot see these tumours to know whether they are increasing in size or shrinking, and attempts at indirect visualization, e.g. by repeated ventriculograms, are often not practicable. Usually a person who is sent for radiation has had some kind of cranial operation, and it is difficult to say how much of immediate benefit results from the surgical procedure, which may be nothing more than a decompression, and how much is attributable to radiation therapy. It would appear that a comparison of survival periods in comparable types of tumour, one group of which had been treated only surgically, and the other by surgery with subsequent radiation, would give some valuable information. Dr. Francis Schiller in our department has recently attempted such an analysis, but even with some 200 cases of verified tumours the individual groups were too small to be of statistical significance. At present most of us rely on impressions, and on the memory of occasional outstanding cases which seem to have responded favourably. More frequently we resort to this kind of treatment because we realize that we are dealing with a problem which is beyond the scope of radical surgery, and I believe this includes most gliomata which constitute the majority of brain tumours.

In selecting cases for radiation treatment, we try to verify histologically every brain tumour, either by open exploration or by needle biopsy. This we regard as of the utmost importance, as on a number of occasions patients who have presented the clinical features of malignant gliomata have proved to have benign and remediable lesions, such as a meningioma, abscess or subdural hæmatoma. No amount of wisdom and neurological experience can make this differentiation as accurately as the surgeon at operation and the pathologist with his microscope. If the tumour proves to be a benign one in an accessible situation we try to remove it, even though we may add slightly to the patient's disability in so doing, by which I mean that a person with focal epilepsy due to a parasagittal meningioma may have his tumour out, but be left with a slight weakness of one leg which he did not have prior to operation. By taking his tumour out, we have saved him from something worse.

If the tumour is a glioma, we are guided by the type of tumour, its situation, the degree of incapacity which it has already caused, and the further incapacity which may be entailed by removal. Thus a patient with an astrocytoma in the right Rolandic area, who is suffering from severe headache, failure of vision, and occasional epileptic attacks, but with little weakness of his limbs, and little mental impairment—for such a patient we would do a decompression to relieve the pressure symptoms, and would arrange for a course of deep X-ray treatment. To attempt a wide removal of such a tumour would almost certainly produce a hemiplegia, and although it might prolong life for a few months or even longer, the tumour would inevitably recur and cause death. This practice applies to most types of gliomata, although there are some situated on or near the surface of the brain in less eloquent sites where removal, as complete as may be to the naked eye, is justifiable and practicable. With these we usually try to arrange for a course of radiation to deal with the microscopic extensions which we know we have left behind. Thus, we have employed radiotherapy pretty extensively and I should like to take this opportunity of thanking Dr. Jupe, Dr. David Barnes, Dr. Fairchild, and Professor Windeyer among others for their help and co-operation.

In general, we have found that the survival period of treated spongioblastoma multiforme is longer than in the untreated cases, although only the "good cases" are sent for treatment. With the more slowly growing types of gliomata—the astrocytoma and oligodendroglioma—the evidence is very difficult to evaluate, because these tumours behave in such an irregular manner whatever is done to them. Thus it is not very unusual for a patient to present himself with a two or three weeks' history of headache and visual impairment, without any gross neurological abnormalities, and the X-rays reveal a huge area of calcification representing a tumour which must have been present for many months or years without symptoms. A decompression alone may relieve

symptoms for a very long time, and if a course of radiation treatment is given there is no way of saying what effect it has had on the tumour. We have one or two cases of oligodendroglioma which have not had a decompression but have been treated with radiation through the intact skull, and they have remained fairly well for periods of three or four years. We have also had some cases of astrocytoma of the basal ganglia which have had simple decompressions followed by radiation treatment with survival periods of three or four years. These tumours are, to some extent, radiosensitive and worth treating.

Three cases of meningioma have been treated by radiation therapy, one in the cerebellopontine angle, one on the upper and posterior surface of the petrous bone, and one in both frontal regions, and only in the last case has there been any improvement. This was a very vascular tumour, with vascular channels in the skull the size of one's little finger, and the patient, a middle-aged woman, became repeatedly exsanguinated at repeated operations to expose and partially remove the tumour. Now after two years and one course of deep therapy, the decompression area is indrawn and she is free from symptoms. However, we have not done a ventriculogram to see whether, or how much, tumour remains.

Our results with the cerebellar medulloblastoma do not differ significantly from those previously published. Our best case looks like being that of a young adult who had a tumour of the upper vermis extending into the left cerebellar lobe completely removed in September 1942. It was thought at operation to be an ependymoma, but histological examination left no doubt that it was a characteristic medulloblastoma. He was thus given a course of deep therapy following operation, and to date there has been no sign of recurrence. One wonders whether we should not more often try to effect a wide removal of these tumours and follow this with a course of radiation treatment—although in those cases in which the floor of the fourth ventricle is involved, or in which there are already meningeal metastases, surgery probably has little to offer.

The cerebellar ependymoma, a tumour which usually grows in the lower part of the fourth ventricle, is often attached to the floor or to the calamus scriptorius, and presents as a mass in the cisterna magna. These are essentially benign tumours, but their situation usually means that complete removal is not possible without doing irreparable damage to the medulla. It has been the experience of most people, however, that a subtotal removal, leaving a fringe of attachment to the calamus will keep these patients free from symptoms for a number of years, if not permanently.

In November 1939 we admitted a little girl aged 7 with a short history of headache, vomiting, unsteadiness in walking, which symptoms confined her to bed within two or three weeks. On examination, there was no enlargement of the skull, intense papilloedema, nystagmus to both sides, ataxy of all four limbs, with in the lower limbs a considerable flaccid weakness and absence of tendon reflexes, sphincteric paralysis, and a good deal of pain in the back. Clinically this looked like a medulloblastoma with spinal metastases. A ventriculogram indicated a tumour in the lower part of the fourth ventricle and she was given a trial course of deep therapy. The result was immediate and dramatic, and was regarded as confirming the diagnosis. Within four or five weeks she had regained her normal health, and it was not possible to demonstrate any neurological abnormalities. She had a relapse about a year later, and again a course of treatment brought about this dramatic improvement. She finally died in a third relapse in December 1943, four years after the onset of symptoms, and at autopsy we found a characteristic ependymoma.

It may be a good idea to give a course of treatment as a routine in these cases.

Have we really any evidence that radiation treatment has an effect on brain tumours? I think anyone who has seen the response of a medulloblastoma to a course of X-ray therapy would say yes. But even with these tumours it is a prolongation of life and not a cure which we achieve. Are brain tumours ever cured by radiation? We have experience of one case in which the answer to that, too, is in the affirmative.

In April 1935 a young woman was admitted to the National Hospital, Queen Square, under the care of Dr. Critchley. She had been in good health until two months before admission when, after a mild attack of influenza, she began to complain of progressively severe headache and vomiting, and she had two epileptic attacks characterized by turning of the head and eyes to the left side, and convulsive movements of the left side of the face and left upper limb. After the second of these there was a progressive weakness of the left side of her body. On examination there was bilateral papilloedema, and a slight but definite weakness of the left limbs and face, with a corresponding alteration in the reflexes. X-rays of the skull were normal, but the spinal fluid pressure was elevated and the fluid contained an excess of protein. There was thus little doubt that there was an expanding lesion in the right frontal region, either a rapidly growing glioma or possibly an abscess. At operation Mr. Hugh Cairns found a subcortical glioma in the right frontal lobe. Sufficient of this was removed for histological examination and Dr. Greenfield demonstrated that it was a glioblastoma multiforme, of a malignant type. There was some improvement after operation, notably in the relief of headache and subsidence of papilloedema, but little alteration in the left-sided weakness. Four weeks after operation a course of radium treatment was given, 44,400 mg.-hrs. (100 mg. plaque) directed to the right frontal region.

Improvement continued until January 1936, when she again began to complain of headache, the decompression became very tense, and the left hemiparesis more marked. In the following month, she had a course of high-voltage deep X-ray therapy (200 kV. 1.5 mm. copper filter; 6,600 r in 14 doses; 5 fields, a.p., 2 lateral, superior, vertical), with a rapid improvement in her general health, abatement of the pressure symptoms, and a slight improvement in the neurological abnormalities. In June 1936 there was a rapid worsening of her symptoms: headache, vomiting, drowsiness, and now a complete paralysis of the left arm and nearly complete paralysis of the left leg. She was given a second course of deep therapy (the same physical factors 16 doses, 7,810 r) and again there was a prompt improvement. By October 1936 she had no symptoms, the decompression area was soft and just flush with the skull, the papilloedema had completely subsided, and there was only a slight kinetic weakness of the left hand with a little sensory impairment in this limb. By March 1937 the decompression area was markedly indrawn. She returned to full work in a shop and in June 1939 she was married. She remained well until September 1941, when her left leg suddenly gave way with her when she was coming downstairs. She thought that she had twisted her ankle, but on attempting to rise (there had been no faintness or loss of consciousness) she found that her left arm and leg were completely paralysed. When she was seen on October 4, 1941, she was unable to walk unassisted. The decompression area was still markedly indrawn, and she had no headache or discomfort but there was a profound spastic weakness of the left arm and leg, and to a less extent of the left side of the face. She remained in about this state until February 1942, when she began to have focal epileptic attacks in the left limbs and left side of the face. In March 1942 she was given another course of deep therapy (9,560 r in fifteen days) which had the effect of stopping the focal epilepsy but she gradually deteriorated and died on July 24, 1942, seven and a half years after the onset of symptoms, and six years after the third course of radiation treatment. At the autopsy there was an extensive subcortical necrosis of the right hemisphere, maximal in the irradiated field. Dr. Dorothy Russell could find no relic of the tumour for which the operation had been done and the radiation therapy given. Thus we must assume that the radiation had killed the tumour completely, but in so doing it produced damage to the normal brain which killed the patient.

We believe this necrosis is a radiation effect and not a very uncommon one. We have encountered some 6 or 8 cases of varying degrees of severity, but there are no means of knowing exactly how often it occurs. The effects may not produce clinical manifestations for many months or years after the radiation, and it is probable that in many cases the tumour kills the patient before these effects have had time to develop. Is this a result of overdosage? In none of our cases was the dosage beyond the accepted range of safety, and it should be said that none of them suffered superficial damage (burns or necrosis) to the scalp or skull, except more or less permanent depilation in irradiated fields. However, most of them were treated through multiple portals of entry, so that no one area of the scalp or skull received more than a fraction of the total dose brought to bear on the tumour.

We have not encountered a similar effect in the spinal cord but there are reports in the literature of such effects. Thus Stevenson and Eckhardt have recently described the case of a man who received radiation treatment for lympho-epithelioma of the neck, and who about a year later developed a transverse lesion of the cord at the fourth cervical segment. This led to his death from respiratory paralysis, and at the autopsy there was a necrotic lesion in the cervical enlargement which had much the same appearance as those we have encountered in the brain. It was estimated that the spinal cord had received between 5,000 and 6,000 r of the total treatment given.

Such an effect of radiation makes me more cautious in advising radiation therapy for a lesion which I am not certain can be treated in no other way.

Thus, some years ago, a middle-aged woman came in suffering from peculiar diencephalic attacks and a mild increase in intracranial pressure. A ventriculogram revealed a slight symmetrical hydrocephalus with a filling defect in the posterior part of the third ventricle which we interpreted as the medial extension of a thalamic glioma. She had a decompression done, with great improvement but because of the supposed site and nature of the lesion, she was given X-ray therapy (3,492 r, 1,908 r, 1,440 r) during the next two years. She died three and a half years after her first admission, and at the autopsy there was a massive subcortical necrosis of the right hemisphere, and the only other lesion found was a small colloid cyst in the third ventricle. The right treatment in this case would have been to withhold the X-ray treatment until we had had more information from further ventriculograms when the decompression was no longer adequate.

The possibility of doing damage with our present technique of therapy raises important problems. What is the maximum dose of radiation the brain will tolerate without these necrotic effects? What dose will have the maximum beneficial effect on the tumour and yet not cause necrosis? Should we revise our views about multiple portals of entry and perhaps concentrate on irradiating a tumour exposed at operation?

Dr. Dorothy S. Russell [Summary]: In the histological examination of gliomas which have been treated by deep X-ray therapy it has been impossible, as a rule, to assess the amount of tissue-damage attributable to the treatment owing to the natural occurrence of variable degrees of necrosis, hæmorrhage and vascular changes in untreated tumours.

It is therefore of fundamental importance to gauge the effects of such irradiation upon the normal brain. Two cases of this kind have been mentioned by Mr. Pennybacker. In the first, of which he gave particulars, symptoms proved to be due to a small colloid cyst of the third ventricle. Irradiation necrosis developed beneath a right temporal decompression. In the second case, in a middle-aged man, symptoms referable to a lesion in the left temporal lobe followed nine months after a single dose of 2,350 r had been given for a rodent ulcer of the overlying scalp.

The *macroscopic* appearances in both cases were similar: there was massive necrosis of the subcortical white matter accompanied by numerous small hæmorrhages, and the overlying cortex was broadened and abnormally tough, especially over the summits of the convolutions. *Microscopically*, the subcortical white matter was completely destroyed through a large part of the lobe by necrosis and hæmorrhage, and the necrosis extended in places into the cortex. The latter showed considerable loss of neurones, complete in places, accompanied by a pronounced gliosis. Many of the perforating blood-vessels had undergone fibrinoid necrosis and were often thrombosed, while others showed great collagenous thickening of their walls. In the meninges there was a trivial degree of fibrous thickening and sparse lymphocytic infiltration. Remarkable features were the diffuse permeation of both grey and white matter by numerous threads of fibrin, and the absence of cortical atrophy in spite of the considerable destruction of the neurones.

Animal experiments.—Dr. C. M. Wilson (Physics Department, Westminster Hospital Medical School) has participated in an attempt to find out in what order these changes take place in the brain, and the part played by alterations in blood-vessels. To this end the left side of the skull in a series of 8 rabbits was irradiated with a single dose of 2,850 r. The animals remained perfectly well until about a hundred days later when neurological disturbances developed (3 animals). One of these, kept alive for a further forty days, became blind and unable to feed itself. These three animals showed cerebral lesions similar to those described in the human cases. The foci of necrosis, however, occupied central parts of the brain and were rarely accompanied by demonstrable vascular changes. The cortex immediately below the site of irradiation appeared relatively insusceptible. The left lobe of the cerebellum showed marked changes in both cortex and white matter in two animals.

The remaining 5 rabbits were killed at earlier stages (seventy-three to ninety days after irradiation), before the onset of symptoms, in order to identify early stages of the lesion. In 2 (at eighty-three and ninety days respectively) such changes were observed. They occupied the cerebellum and hippocampus and consisted of minute hæmorrhages. Necrosis of tissue and early focal gliosis were sometimes associated, but no histological alterations were observed in the blood-vessels. It is therefore difficult to attribute the necrosis and hæmorrhage to vascular damage, as appeared likely in the human material. The investigations are being continued, and will be reported later in full. In conclusion the following questions require an answer: What is the significance of the prolonged latent period before the lesions develop? Why are the lesions progressive when they are once initiated? And why, in the experimental animals, are the lesions deep-seated in the cerebrum and not superficial? The answers may be found by the physicist; they appear at present to be insoluble to the pathologist.

Mr. J. Jackson Richmond: There are three problems related to this interesting subject which I would like to discuss briefly. First, the difficulty in selection of cases for irradiation treatment. Dr. McWhirter has stressed the importance of a histological classification in deciding the question. However, very often one meets with surprises. For instance, it is generally stated that the astrocytoma is a radio-resistant tumour, but this is only true when considered as a group. Occasionally these gliomas prove to be relatively radiosensitive. Again it is difficult to assess suitability according to the patient's general clinical condition. Sometimes palliation of years standing follows treatment of patients seemingly in dire straits. This occurs usually but not always with classically radiosensitive tumours, e.g. spongioblastomata or medulloblastomata. Therefore in the light of present knowledge, I accept for treatment a great majority of the cases referred by neurosurgeons unless, of course, the patient is *in extremis*.

Secondly, "Is it worth while giving a second course of irradiation treatment in the case of recurrence following previous radiotherapy?" For the great majority of these cases the answer is "no" but very occasionally it is a justifiable procedure. Although many features of the case will influence the decision, I consider that the most important single factor is the interval of clinical freedom from active disease following the original treatment. If this period is three years or more and the tumour dosage given in the first instance was conservative, then further treatment may arrest the progress of the disease for an appreciable time.

The third point is the importance of irradiating a sufficiently extensive zone of brain tissue to ensure bringing the entire growth to full dosage level. In many cases, clinical localization of the tumour even with the aid of ventriculographic studies can only be approximate. Very often, after surgical exploration, it is impossible to delimit the extent of an invasive tumour. With this in mind it is possible to establish a series of standard regional irradiation techniques which can be modified when necessary to suit individual cases.

Slides were shown illustrating "X-ray field systems" and dosage contours to conform to the above principle. Also an apparatus recently adopted in the treatment of cerebral tumours was briefly described. This was designed to set up a predetermined field of uniform irradiation and at the same time ensure maintenance of beam direction.

Dr. Frank Ellis: I should like to thank the opening speakers for their admirable papers. One point which must be appreciated by all dealing with cerebral tumours is that histological evidence is essential to decide on, and learn from, the treatment given. I should like to ask Dr. McWhirter whether he can be sure that the cases he did not treat with radiation were not radiosensitive, even if his judgment regarding the cases he did treat was considered justified by results. I think that for the present, more evidence is necessary, and that his non-sensitive groups should be treated until the evidence is irrefutable.

Comparatively recently normal nervous tissue was considered insensitive to radiation. In 1934, following treatment for carcinoma of the œsophagus with one of the fields centred over the spinal cord, a patient of mine developed a transient paraplegia. Thinking this might be due to the radiation I consulted the literature and found it teeming with evidence of the damage which can be done by radiation to normal nervous tissue. Most of the histological appearances seemed to consist of focal necroses but they seemed to depend for their nature on the dose and the time after treatment at which the examination was made as well as the age of the animal. Functional changes were also described, especially from Pavlov's Institute by Nemenow, using the disturbance of conditioned reflexes as a criterion. Dr. Russell's experiments showing the increased permeability of the capillaries to a dye soon after radiation are in accord with the accepted view of the effect of radiation. It is an indication that the efficiency of nervous tissue might be seriously influenced by radiation because the resulting disturbance of nutrition might have serious effects. As a student of physiology, I was, for instance, much impressed by the sensitivity of the brain to oxygen lack. The idea has occurred to me that the recurrence of symptoms following treatment might be due to such changes as those described by Dr. Russell occurring, as might be expected, in the region of the tumour. In 7 cases out of 50 treated in the last two-and-a-half years there seems to be reasonable evidence of this. In such cases, further treatment might possibly increase the damage rather than be good for the patient. The doses given have been rather small than otherwise (3,500 to 4,000 r in about three to four weeks). The region treated was usually about 2 cm. beyond the supposed limits of the tumour as indicated by the neurological surgeon. It might be that the extensive necrosis reported by Mr. Pennybacker in his cases was associated with the very high dosage and the frequent treatments.

The immediate effects of radiation in causing improvement when this occurs, might conceivably be due to an inhibition of the secreting activity of the chorionic epithelioma.

Mr. J. E. A. O'Connell: I have been interested in the effects of X-radiation upon the tissues of the central nervous system and was fortunate in having the opportunity of working on this subject in Dr. Percival Bailey's laboratory in Chicago. The results of this investigation were published (O'Connell and Brunschwig, *Brain*, 1937, 60, 230). It has been suggested that the changes in the nervous tissues may be secondary to vascular changes produced by irradiation. The histological changes observed in our investigation were less severe than those mentioned by Dr. Dorothy Russell, but were otherwise of very similar type. In the brains which we examined the evidence of damage to the blood-vessels was slight—an excessive quantity of fat in the walls of the capillary blood-vessels being the only common one. We were therefore led to the conclusion that both the vascular and the nervous damage resulted directly from irradiation and that the latter was not secondary to the former. Secondly, one speaker has suggested that it might be beneficial if brain tumours were irradiated at the time of the operation with the bone flap reflected from the surface of the tumour. This procedure has been carried out in the United States—but not, as far as I know, with benefit. Since it seems likely that the intensity of irradiation is as important a factor as total dosage in producing damage in normal tissues such irradiation at the time of operation might well be unwise on theoretical grounds.

Section of Dermatology

President—SYDNEY THOMSON, M.D.

[April 18, 1946]

Folliculitis Decalvans.—H. CORSI, F.R.C.S.

Male, aged 40.

This patient shows extensive ordinary baldness. In addition, there is, at the sides and back of the scalp, marked loss of hair. The loss of hair is of the parvi-maculata design, somewhat similar to that seen in Brocq's pseudopelade. The whole area, however, shows considerable erythema, and only a few weeks ago many of the follicles were pustular. The beard area and moustache area are normal.

The patient was given Fowler's solution \frac{mii} three times a day, for two months, and it was during and subsequent to this that the acute activity in the follicles ceased.

A Wassermann test was negative.

On the whole the case appears to be the type of folliculitis decalvans described by Quinquaud, but the even distribution of the bald patches is atypical, and there is possibly an alternative diagnosis which could be suggested.

POSTSCRIPT.—Subsequent examinations for favus or other fungus proved negative.

Dr. F. F. Hellier: I have seen recently a case of scarring alopecia which was due, as far as I could make out, to tropical lichenoid dermatitis. The man had lichen-planus-like lesions on his body, face, and scalp. He had been taking mepacrine and had been in West Africa. Has any member seen one of these cases of scarring alopecia and watched it right through to a finish? I have not done so myself and I should like to know the prognosis.

Dr. G. B. Mitchell-Heggs: I have under my care a student with folliculitis, loss of hair and scarring, involving the scalp and eyebrow. Bacteriological examination of the hair follicles revealed a staphylococcus, resistant to penicillin, but sensitive to sulphathiazole. The latter was prescribed, and the condition has improved. It is perhaps early to discuss cure, as only three months have elapsed. Except for involvement of eyebrow, it is similar to Dr. Corsi's case.

? **Acne Conglobata.**—H. J. WALLACE, M.D.

Miss G. C., aged 30, Secretary.

The patient has noticed small nodules in various parts of the body for the past thirteen years some of which grow for a time and then disappear; others she thinks have been persistent. They first appeared in the right axilla thirteen years ago. They usually grow for about six weeks and then burst, discharging yellowish pus. Most other parts of the body have been affected from time to time. Recently the lesions have been most prominent in the peri-anal area, and it was for a series of sinuses, resulting from discharging nodules, in this area, that she sought advice. She is at present under the care of Mr. Boggon at St. Thomas's Hospital. One nodule with sinus was excised, with the following pathological report:

"Sections show a filterless tract in the subcutaneous tissue and communicating with the surface. There is an acute and subacute inflammatory reaction with polymorphs, plasma cells and fibroblasts numerous. Gram-stained section shows a number of Gram-positive globoid bodies resembling monilia (yeasts). No cocci seen. The inflammatory reaction extends for some distance into the surrounding tissue."

Pus from one of these lesions showed *Staphylococcus aureus*. Another nodule has been excised; histology was typical of a sebaceous cyst.

On examination.—Nodules with much scarring, together with sinus formation, can be seen especially in the buttock, together with other typical nodules in the skin, particularly on the trunk.

Comment.—This condition is well marked in the patient's family. She has five brothers and four sisters, of whom two brothers and two sisters are afflicted but in lesser degree, and in some the process seems to have died out.

Dr. F. Parkes Weber: There can be no doubt that this interesting case is one of what has been termed "sebocystomatosis" or "steatocystoma multiplex". I do not see why one should not call it by the third or common name, "hereditary sebaceous cysts", though the sebaceous cysts are not limited to the scalp. The dominant Mendelian heredity and the great number of relatives affected are typical.

In the present patient some of the sebaceous cysts have become secondarily infected with pyogenic organisms and the resulting suppuration has been associated with a tendency to sinus formation.

A most interesting feature in this particular case, is its association, mostly in the spring, with what can be called recurrent suppurative hidro-adenitis axillaris, which is well known and not rare. The association may, however, be a chance one. I am not sure whether there is any connexion between the sweat gland disease and the hereditary sebaceous cysts.

The complication of the suppurating sinuses in the fat region of the buttocks is a very disagreeable feature of the case.

Dr. F. F. Hellier: There are one or two points which I might recall concerning a case I described in 1939 (*Brit. J. Derm.* (1939), 51, 109). The man had a severe acne over his whole back, right down on to the buttocks, with tunnelling and sinus formation, and characteristic bridge-scars. The diagnosis was not in doubt. He had many cysts and, in reference to what Dr. Parkes Weber has said, I am sure that his acne was not due to sebaceous cysts. He had enormous scarring over the whole back and isolated sebaceous cysts. I feel that there were two conditions—the cysts and the acne lesions—running side by side.

When I saw the first of my cases with cysts, I wondered whether they were retention cysts, caused by the scarring. I began to look up the man's family. I found a sister in a local asylum with a lesion like a rhinophyma, exactly like her brother, and a large cyst hanging pendulously from her ear. I felt it unlikely that there could be a retention cyst and scarring on the lobe of the ear, and I considered it was a congenital cystic condition. All the family had a marked degree of what one might describe as *kérose*. I think another member had also been in an asylum and they were all of rather low mentality. This may have been a coincidence; it was obviously running through the family. I feel there was some underlying fault in the germ plasm which had led to a series of defects.

Dr. A. C. Roxburgh: The case seems to me to be much more an infection of the sweat glands than one of a sebaceous nature. It is not in the least like a case of *sebocystomatosis* I saw in 1938. That woman had a large number of cysts over the sternum, anterior axillary folds and round the lower thorax, all of which contained a peculiar oily kind of grease. I should not think this was even a case of *acne conglobata*.

The President: One point about the case is that the woman's back, particularly on the right side, shows some small tumours in the dermis which are not, apparently, connected in any way with the conglobata lesions, but which are rather bluer and more translucent. Those reminded me of *syringomata*.

Eosinophilic Granuloma.—C. L. COLLINS, M.B.

Mrs. E. H., aged 38, had noticed a small swelling in the left groin about seven weeks before I saw her in Dr. Duckworth's clinic at St. John's Hospital, a few weeks ago. During the seven weeks the swelling had increased and had become a small tumour, painless, circumscribed, oval, dusky red, and soft.

The tumour was excised and the microscopical findings were as follows: There are foci of reticulum cells in the corium, especially in the upper fourth. These foci are infiltrated with and surrounded by eosinophilic cells.

×35

×175

Eosinophilic granuloma.

The white cell count was: W.B.C. 12,400 per c.mm., of which 68% were polymorphs; 4% eosinophils; 28% lymphocytes; no monocytes seen. This white cell count contrasts with that seen in previous cases, described by A. Pasini (*G. ital. Derm. Sif.*, 1940, 81, 1) and P. Cerutti (*Dermatologica*, 1942, 85, 90), in which there was a morbid eosinophilia, amounting to 40%.

Lichen Sclerosus et Atrophicus (Lichen Planus Morpheicus).—BERNARD GREEN, M.R.C.S., L.R.C.P.

Miss D. B., aged 17 years.

The first lesion commenced about six years ago as a small papule over the right scapula: A few more papules appeared slowly and about eight months ago the condition began

to spread. The lesions now consist of two main plaques situated over the right scapula, composed of irregular, slightly elevated, flat topped, mother-of-pearl papules. In addition to the two main plaques there is a number of discrete papules scattered across the shoulders. Some show a slight depression in the centre; others have a horny comedo-like plug in the centre situated at the pilosebaceous orifices. Atrophy is present as a tissue-paper-like wrinkling, simulating that seen in atrophic forms of morphea. Her general health is good and there is nothing to suggest any endocrine disturbance.

This condition is said to be a distinct entity. It is more common among women and is said to occur more frequently in the later stages of life.

Atrophic forms of lichen planus can simulate this disease, but usually one can find some typical lichen planus papules in some of the lesions. In addition lichen planus is much more rapid in its development. I think, therefore, that the name lichen sclerosus et atrophicus is more suited to this complaint than lichen planus morpheicus.

Histological report.—The epidermis is thinned and covered by a thickened stratum corneum which also extends into the lanugo follicles. The collagen in the superficial layer of the corium is homogeneous and condensed.

Dr. F. Parkes Weber: This is an example for those who would like to believe that lichen sclerosus et atrophicus is a variety of morphea. It may be called "lichen sclerosus et atrophicus", but I suggest that it may justifiably be regarded as what I would term "morpheic scleroderma of the lichen sclerosus et atrophicus type".

The President: I remember one similar case shown many years ago in regard to which Dr. Sibley made the clinical diagnosis. Subsequently a biopsy was done and to everyone else's surprise there was a definite lichen planus histology.

Dr. H. Corsi: So long as we remain in ignorance of the nature of many skin diseases, the terms by which we designate them are mostly mere statements of physical signs. In that group of physical signs which we call lichen planus, the cases are as a rule typical, so that there is no difficulty in diagnosis. If the case is atypical, there will be, in most instances, the unmistakable papule of lichen planus discoverable somewhere; so that even if the major portion of the eruption is horny, or atrophic, or vesicular, it is still recognizable as an example of the disease we call "lichen planus".

In 1915 Sir Ernest Graham-Little began to show a series of cases of atrophic spinulosis of the scalp, without affection in any other part of the body. The subject "syndrome Graham-Little" has been taken up in foreign literature in relation to the pseudopelade described by Brocq. Coincidentally I have come across this literature in reading up the subject of folliculitis decalvans in connexion with the case of atrophic folliculitis of the scalp which I have shown here to-day.

In 1937¹ I showed a case of lichen spinulosis of the scalp, type Graham-Little, at this Section. This patient had lesions typical of lichen planus and also suffered from a vesicular eruption about the nails of hands and feet. The nails fell off and never grew again—another rare manifestation of "lichen planus". I was able to show a similar case a month later, though I have never seen another since. From my two cases, and from certain other cases described in foreign journals,¹ it seems fairly certain that atrophic lichen spinulosis of the scalp, atrophic onychomadesis, perhaps also white-spot disease, and therefore some forms of scleroderma, are all varieties of that disease, which, from its most frequent physical sign, we call "lichen planus".

It seems that "lichen planus" may show almost every physical sign which can be met with in dermatology, and it appears to me that Dr. Green's case of atrophic or sclerotic spinulosis of the skin of the back can very well be an atypical form of lichen planus.

¹ See Bibliography under Corsi: Atrophy of Hair Follicles and Nail-Matrix in Lichen Planus. *Brit. J. Dermat.*, 1937, 49, 376-384.

Linear Nævus Treated by Thorium X.—P. J. FEENY, M.B.

J. R., a girl aged 10 years.

A linear nævus, maximum length $1\frac{1}{2}$ in., maximum width 2 in., was present on the outer surface of the right upper limb. Test areas had been treated by CO₂ snow, sodium morrhuate injection and radium plate; the main mass had then been treated by thorium X, affording an opportunity for comparing their merits in this type of case (i.e. the mixed type). The nævus extended from the middle of the outer surface of the right arm down the outer surface of the forearm and the back of the hand to the nail-fold of the forefinger (the nail being split longitudinally) and ended on the middle finger at the level of the proximal interphalangeal joint. It was first noticed at the age of eighteen months.

Treatment.—CO₂ to marked area on arm when aged 6½ years. A month later had sodium morrhuate injection to another marked area on the arm. At age 8 had 8 mg. radium plate to the marked area at the edge of the lesion halfway down the forearm. This test area showed atrophy and telangiectases.

Ten months ago treatment by thorium X was commenced, 1,500 e.s.u. per c.c. in varnish once a month. For the past three months, the portion on the hand and fingers has been treated fortnightly, last treatment a week ago.

The response was immediate and noticeable after the first treatment. It has been so satisfactory that no further treatment is necessary.

[May 16, 1946]

Lichen Sclerosus.—GODFREY BAMBER, M.D.

T. G., aged 14. The first lesions on this girl's skin appeared two and a half years ago on the front of the left hip and on the back of the right thigh, and a little later on the fronts of the ankles. Later lesions developed near the point of the right elbow, and over the left scapula. These lesions were said to be white and slightly scaly. About six months ago white lines began to show on the outer side of the right arm. The general health has been good.

The appearance of the larger plaques when I first saw her in January last had been altered by treatment with thorium X, but that of some of the smaller lesions was characteristic of lichen sclerosus, a white shiny surface with some scaling and pitting.

The linear lesions on the arm are an unusual feature of this condition. The finest looked nothing more than thin lines of depigmentation, but when some of the wider ones were examined with a lens the surface looked somewhat shiny and a little atrophic. So far no scaling has developed on these linear lesions.

Histology.—A piece was removed from the lesion near the right elbow, and the section confirms the diagnosis.

POSTSCRIPT (21.8.46).—When the patient was seen recently the linear lesions were less apparent.—G. B.

Dr. W. Freudenthal: It would be worth while to examine these fine streaks histologically.

Dr. F. Parkes Weber: I think that one ought to call these cases "morphœic sclerodermia of the lichen sclerosus et atrophicus type". I think these cases represent a variety of morphœic sclerodermia and that "lichen sclerosus et atrophicus" is a more recent term which should not be allowed to displace the older and more inclusive term, "morphœic sclerodermia".

Dr. A. C. Roxburgh (chairman): The question seems to be whether lichen sclerosus is essentially an atrophic lichen planus or a scleroderma. The evidence seems to be accumulating that it is more of a scleroderma than a lichen planus.

Calcinosis Circumscripta.—GEOFFREY DUCKWORTH, M.R.C.P., and M. GROSSMANN, M.D.

Mrs. M. C., aged 50. Since March 1945 has complained of swollen and painful finger tips; lassitude; "rheumatism" in the knees; and indigestion occasionally. For fifteen years the fingers have exhibited Raynaud's phenomenon when exposed to cold, even of a mild degree.

On examination.—The tips of the fingers are seen to be enlarged, and shining through the epidermis are irregularly shaped whitish macules of a fairly hard consistency. These are present also on the inner side of the little finger of the left hand. They are made much more prominent by squeezing the adjoining tissues. On the right knee, in front, is a red patch of chronic eczema. There are no signs of scleroderma, or dysphagia.

One of these painful white nodules ulcerated through the skin. Another was excised and found to consist of lime salts (the carbonate and phosphate of calcium). A biopsy revealed a curious picture—deep in the cutis was an epidermoid cyst of the implantation type, extending to the surface (fig. 1). Unfortunately it was empty when examined

FIG. 1.—Calcinosis circumscripta. Section showing the curious cyst with its epidermal lining, deep in the corium. $\times 5$.

microscopically. A blood-count showed: R.B.C. 4.75 millions per c.mm.; Hb. 95%; C.I. 1.0. Total W.B.C. 4,550 per c.mm. **Differential:** Polys. 59%, lymphos. 29%, monos. 9%, eosinos. 3%, basos. nil. No abnormal types of cells were seen. The blood calcium was 11.1 mg. per 100 c.c.; phosphorus 4.5; and uric acid 3.5. The W.R. was negative.

Her past medical history was uneventful. Menopause six years ago.

The X-ray appearances are typical of calcinosis circumscripta. The other parts of the skeleton show no evidence of any abnormal calcification, in particular the elbows and knees where such calcifications are described in the condition of scleroderma and Raynaud's disease.

Why such a condition should occur is not known, but there is an interesting account of the pathogenesis in a paper, Cutaneous and Subcutaneous Calcinosis, by F. R. B. Atkinson and F. Parkes Weber (1938) *Brit. J. Derm.*, 50, 267.

Dr. M. Grossmann: The X-ray appearances of Dr. Duckworth's case are typical of calcinosis circumscripta (hypodermololithiasis, Kalkgicht).

There are dense granular opacities in the soft tissue shadows, chiefly of the terminal phalanges, surrounding the tufts (lateral views show that the opacities are situated on the flexor aspect).

Similar small nodular opacities are present at the radial aspect of the middle phalanges of the right index and middle finger (fig. 2).

FIG. 2.

FIG. 3.

A linear, partly lobulated calcium deposit is shown at the radial aspect of the right little finger and irregular calcifications at the radial aspect of the middle phalanx of the left index and the proximal phalanx of the left little finger.

The soft tissue shadows of the hands show no other abnormality of note.

The metacarpophalangeal and interphalangeal joints show very slight lipping of the joint surfaces, suggesting early osteo-arthritic changes.

There is no other bony abnormality noted, in particular no evidence of absorption of the cancellous tuft of the phalanges nor any osteoporosis.

These radiological appearances may be produced by: Thrombo-angiitis obliterans, Raynaud's disease, scleroderma, sclerodactylia.

[May 16, 1946]

Lichen Sclerosus.—GODFREY BAMBER, M.D.

T. G., aged 14. The first lesions on this girl's skin appeared two and a half years ago on the front of the left hip and on the back of the right thigh, and a little later on the fronts of the ankles. which was sensitive to sulphathiazole but quite insensitive to penicillin. The hairs and scalp were examined for favus, but this was negative. He was given a course of sulphathiazole four-hourly for seven days, and from that time until a month or two ago he had used simple sulphur ointment, which brought about improvement, and up to the present time he had had no further extension and no further hair loss. I might add that last weekend he spent two days sun-bathing, following which he got a dermatitis on his face and neck which has since subsided. It was thought that that was due to photo-sensitivity from his sulphonamide.

Bowen's Disease associated with Anaplastic Carcinomatous Tumour.—G. B. MITCHELL-HECCS, F.R.C.P., and K. D. CROW, M.B.

Woman, aged 57. In 1936 she developed an irritating rash, so-called, on the inner aspect of the left thigh, and this gradually extended until in 1942 a lump developed in the centre of it. As far as we can gather, the lesion was composed, in the first place, of rather small nodules. About this time she had a lot of crusting, and the crusts when removed showed oozing and bleeding underneath. She was admitted to hospital in 1945 and the tumour was excised from the centre of the lesion and an inguinal lymph gland which was enlarged was also removed. The biopsy from the tumour in the middle of the lesion and the lymph gland both showed anaplastic squamous carcinoma. Her Wassermann reaction was negative, and there was nothing relevant in her previous history. This case has been shown for views on the most suitable treatment, but the treatment which has been contemplated is a wide excision followed by skin-grafting.

Histology.—(Professor W. D. Newcomb): Many large and irregular cells, some undergoing mitotic division in the epidermis. Many lymphocytes in papillary layer of dermis.

The Chairman: Is it usual for Bowen's disease to show these oozing surfaces? Are there any suggestions for treatment? How do these cases respond to radiotherapy? If I had one myself I would prefer surgical excision.

Dr. A. N. P. Milner: These cases are supposed not to respond to radiotherapy. Recently a case was sent to me which had failed to respond to treatment by a radiologist.

Two Cases of Folliculitis Varioliformis and Dermatitis Papillaris Capilliti.—A. N. P. MILNER, M.D.

I have shown these two cases to draw attention to certain similarities which suggest that they are not separate entities. They and also the condition known as perifolliculitis abscedens et suffodiens may, I think, be regarded as complications of a primary destructive folliculitis typified in its mildest form by folliculitis varioliformis.

Both cases suffered from acne vulgaris for some years prior to the onset of the scalp condition and, in each case, after development of the scalp condition, the acne vulgaris became quiescent. Both exhibit cribriform scars and indurated nodules; in the former case, pitted scars and, in the latter, nodules predominate. The early lesions of both conditions consist of brownish-red papules pierced by hairs which develop into sluggish pustules capped by scales. Perifollicular spread is common to both and demonstrated by confluent pitted scars in the former and by hypertrophic fibromatous nodules and inter-connecting bridges in the latter.

The section from the case of dermatitis papillaris capilliti displays marked folliculitis and perifolliculitis with a deep-seated fibromatous reaction in the corium.

Seborrhœic Sycosis.—A. N. P. MILNER, M.D.

I have shown this case in antithesis to the other two. Seborrhœic sycosis does not form follicular scars on healing and does not occur apart from seborrhœic dermatitis or a history of a recent attack of this disease. The inflammatory process is largely perifollicular and not destructive of the hair follicles. The infecting agents, staphylococci, are the same in both seborrhœic sycosis and destructive folliculitis of the scalp. The seborrhœic factors seem to protect the follicles in some way not understood. The alopecia pityroides, so called, often found in association with acne vulgaris and seborrhœic conditions, is more probably due to endocrine disorder brought about by overactivity of the sex glands and will usually respond to stilbœstrol. The seborrhœic condition is probably coincidental rather than causative in this form of alopecia.

Dr. C. H. Whittle: I showed a case in an Italian prisoner of war a year ago which I think would probably be classified as a cicatricial sycosis. The appearance in the hair margin was very similar to that seen in one of Dr. Milner's cases. It had resisted all forms of treatment for years, but one of the members at the meeting suggested penicillin locally, and this was tried. The patient, who lives at a distance, writes gratefully to say that the local application of penicillin cream clears up the condition quickly, but it does not remain clear for very long without further treatment.

Some authors have observed similar deposits in lupus vulgaris and erythematodes. Other sites should be examined as similar opacities may be present about the elbows and knees.

Dr. Grossmann showed slides of a case where calcareous deposits were found in the hands of a woman, aged 56, suffering from syringomyelia. This patient developed Morvan's disease of the right hand; in 1941 a whitlow of the tip of the right middle finger was opened and chalky material removed (fig. 3).

In March 1946 the patient attended again for a recurrence of the swelling of the finger.

The radiograph of her hands shows some osteoporosis of the joints with osteo-arthritic changes, but no radiological evidence of such changes as are commonly observed in neuropathic joint lesions with disorganization of the articular surfaces. There is, however, an osteolytic process of the tufts of the terminal phalanges of the left index and ring finger and the right index and little finger giving them a short and pointed appearance caused by partial absorption commencing distally. Extensive calcification is present in the palmar aspect of the terminal phalanges of most of the fingers of the right hand and of the proximal phalanx of the thumb. The distal interphalangeal joints of the left thumb, index and middle finger and the tip of the left little finger show minute calcified deposits.

Calcification in neuropathic joints may appear near the affected joints but is rarely seen in the tip of the phalanges.

Dr. F. Parkes Weber: Some of the earlier cases of cutaneous and subcutaneous calcinosis were published by myself, with or without other doctors. Dr. Duckworth's and Dr. Grossmann's cases are to my mind examples of calcinosis in the fingers occurring in individuals with Raynaud-like symptoms in the hands—i.e. patients subject to "dead fingers." Both patients (including the one with syringomyelia) have had recurrent Raynaud-like symptoms. The commonest type of calcinosis in the fingers is that associated with the sclerodactylia type of scleroderma, which is nearly always accompanied (at some stage) by Raynaud-like symptoms. The rare cases of Drs. Duckworth and Grossmann help to illustrate the whole subject of finger-calcinosis.

Dr. H. D. Haldin-Davis: I should like to know whether there was any calcinosis around the olecranon. About thirty-five years ago I had a case of a youngish woman with calcification of the fingers and around the olecranon. That case was also seen by Dr. Parkes Weber. She died not long afterwards, although apparently a healthy woman at the time I saw her.

Dr. F. Parkes Weber: I have no doubt that I could find amongst my notes and cuttings the case to which Dr. Haldin-Davis has alluded, but I have got a large collection. Perhaps I may be allowed to add a word about the so-called dermoid cyst in the finger. I cannot admit that it is a dermoid cyst in the ordinary sense of the term. I should explain it as a necrobiotic change accompanying and preceding the calcareous deposition. Without that change the calcareous deposit would not be present. The necrobiotic change permits the deposition of calcium salts. After a time the necrobiotic tissue becomes actually necrotic, not merely necrobiotic, and as a foreign body becomes surrounded by a fibrous capsule. Ultimately the calcareous material may be extruded like a foreign body or the uratic contents of a gouty tophus.

Telangiectasia Macularis Eruptiva Perstans.—G. B. MITCHELL-HEGGS, F.R.C.P., and K. D. CROW, M.B.

Man, aged 47, clerical worker. His condition commenced in 1928, when he noticed an eruption of purpuric-like lesions around the ankles. These faded and left persistent brownish-red stains, involving later his legs, thighs, abdomen and a few on the arms. Fresh lesions had erupted and the patient thought that at different times some of the older lesions became redder. He had a severe gum infection.

He was seen by Dr. Mitchell-Heggs in February 1946 and it was then considered that the essential lesion was a telangiectasia rather than a pupura. He did not take any drugs. He had had pulmonary tuberculosis, but had had no gold therapy for it. There was no family history of telangiectasia or other hæmorrhagic disease. When first seen he had a generalized eruption consisting of telangiectatic areas and other orange-red or even brownish macules about 1 or 2 mm. across. At no time was urtication demonstrated, and the blood-count was normal, as were the clotting and bleeding times. A biopsy showed perivascular infiltration in the upper part of the corium.

Dr. F. Parkes Weber: As regards the diagnosis, I agree that this is a case of what I thought ought to be called "telangiectasia macularis eruptiva perstans," but it is a very rare type. The ordinary cases are in very fat, florid women, and the symptoms appear rather later in life than in this man. Osler, however, published a case in a male which was probably of this kind, but under quite a different name. Anyhow, there are rare cases in men, probably commencing at a younger age than those typical ones in women. I would like to emphasize the complete absence of urtication in the present case and I am looking forward, of course, to the biopsy report in regard to tissue mast-cells in the lesions.

Folliculitis Decalvans associated with Penicillin-resistant *Staph. aureus* Infection.—G. B. MITCHELL-HEGGS, F.R.C.P., and K. D. CROW, M.B.

In 1943 a medical student aged 23 came to see Dr. Mitchell-Heggs complaining of increasing baldness. He had thin wiry hair, and there were areas where the hair was completely absent. He also had diffuse thin eyebrows. On examination of the hair it was found that deeper down in the follicle there was in fact pus. The hairs were fairly formed, but bacteriological examination showed a pure growth of *Staph. aureus*

which was sensitive to sulphathiazole but quite insensitive to penicillin. The hairs and scalp were examined for favus, but this was negative. He was given a course of sulphathiazole four-hourly for seven days, and from that time until a month or two ago he had used simple sulphur ointment, which brought about improvement, and up to the present time he had had no further extension and no further hair loss. I might add that last weekend he spent two days sun-bathing, following which he got a dermatitis on his face and neck which has since subsided. It was thought that that was due to photo-sensitivity from his sulphonamide.

Bowen's Disease associated with Anaplastic Carcinomatous Tumour.—G. B. MITCHELL-HEGGS, F.R.C.P., and K. D. CROW, M.B.

Woman, aged 57. In 1936 she developed an irritating rash, so-called, on the inner aspect of the left thigh, and this gradually extended until in 1942 a lump developed in the centre of it. As far as we can gather, the lesion was composed, in the first place, of rather small nodules. About this time she had a lot of crusting, and the crusts when removed showed oozing and bleeding underneath. She was admitted to hospital in 1945 and the tumour was excised from the centre of the lesion and an inguinal lymph gland which was enlarged was also removed. The biopsy from the tumour in the middle of the lesion and the lymph gland both showed anaplastic squamous carcinoma. Her Wassermann reaction was negative, and there was nothing relevant in her previous history. This case has been shown for views on the most suitable treatment, but the treatment which has been contemplated is a wide excision followed by skin-grafting.

Histology.—(Professor W. D. Newcomb): Many large and irregular cells, some undergoing mitotic division in the epidermis. Many lymphocytes in papillary layer of dermis.

The Chairman: Is it usual for Bowen's disease to show these oozing surfaces? Are there any suggestions for treatment? How do these cases respond to radiotherapy? If I had one myself I would prefer surgical excision.

Dr. A. N. P. Milner: These cases are supposed not to respond to radiotherapy. Recently a case was sent to me which had failed to respond to treatment by a radiologist.

Two Cases of Folliculitis Varioliformis and Dermatitis Papillaris Capilliti.—A. N. P. MILNER, M.D.

I have shown these two cases to draw attention to certain similarities which suggest that they are not separate entities. They and also the condition known as perfolliculitis abscedens et suffodiens may, I think, be regarded as complications of a primary destructive folliculitis typified in its mildest form by folliculitis varioliformis.

Both cases suffered from acne vulgaris for some years prior to the onset of the scalp condition and, in each case, after development of the scalp condition, the acne vulgaris became quiescent. Both exhibit cribriform scars and indurated nodules; in the former case, pitted scars and, in the latter, nodules predominate. The early lesions of both conditions consist of brownish-red papules pierced by hairs which develop into sluggish pustules capped by scales. Perifollicular spread is common to both and demonstrated by confluent pitted scars in the former and by hypertrophic fibromatous nodules and inter-connecting bridges in the latter.

The section from the case of dermatitis papillaris capilliti displays marked folliculitis and perfolliculitis with a deep-seated fibromatous reaction in the corium.

Seborrhœic Sycosis.—A. N. P. MILNER, M.D.

I have shown this case in antithesis to the other two. Seborrhœic sycosis does not form follicular scars on healing and does not occur apart from seborrhœic dermatitis or a history of a recent attack of this disease. The inflammatory process is largely perifollicular and not destructive of the hair follicles. The infecting agents, staphylococci, are the same in both seborrhœic sycosis and destructive folliculitis of the scalp. The seborrhœic factors seem to protect the follicles in some way not understood. The alopecia pityroides, so called, often found in association with acne vulgaris and seborrhœic conditions, is more probably due to endocrine disorder brought about by overactivity of the sex glands and will usually respond to stilbœstrol. The seborrhœic condition is probably coincidental rather than causative in this form of alopecia.

Dr. C. H. Whittle: I showed a case in an Italian prisoner of war a year ago which I think would probably be classified as a cicatricial sycosis. The appearance in the hair margin was very similar to that seen in one of Dr. Milner's cases. It had resisted all forms of treatment for years, but one of the members at the meeting suggested penicillin locally, and this was tried. The patient, who lives at a distance, writes gratefully to say that the local application of penicillin cream clears up the condition quickly, but it does not remain clear for very long without further treatment.

Parapsoriasis.—BRIAN RUSSELL, M.D.

A married woman, aged 39, with a non-irritating rash on the calves and forearms which began in the summer of 1944, later spreading to the arms and thighs. She attributed it to emotional disturbances in connexion with flying bombs. On examination, the almost confluent, slightly scaly discs on all limbs, some showing depressed yellow adherent scales, do not give any bleeding points on scraping. There is no family history of psoriasis and the blood Wassermann and Kahn reactions are negative. The lesions improved very slightly with ultraviolet light therapy. The diagnosis of parapsoriasis is made because of: (1) Complete lack of irritation; (2) the presence of scaly, somewhat psoriasiform lesions but without bleeding points on scraping; (3) a distribution not typical of psoriasis; (4) lack of involvement of the nails and scalp; and (5) the intractability of the condition which has responded little, if at all, to ultraviolet light or other treatment.

The patient is anxious about her condition and suggestions as to treatment would be welcome.

Dr. Parkes Weber: This case is one of "parapsoriasis" as a symptom-term, in the sense that the clinical appearance is somewhat like psoriasis. I suggest that in this patient the condition is really one of true psoriasis, though symptomatically somewhat atypical, and that treatment should be carried out in accordance with this view.

Lichen Planus Atrophicus.—BRIAN RUSSELL, M.D.

The patient is a soldier, aged 25, with an irritating circular lesion on his right breast of ten months' duration which previously had been treated with iodine. On first examination of the polycyclic depressed bluish area, with comedo-like plugs in several follicles and with a pink, slightly scaly, raised edge, tinea circinata was excluded microscopically and a tentative diagnosis of erythema annulare centrifugum or of érythème fixé was made. There was, however, no history of ingestion of phenolphthaleïn or other drugs liable to produce the latter eruption. On his second attendance a solitary papule of lichen planus was found on the front of the wrist. The patient also now shows annular lesions on the left shoulder and on the penis, without pigmentary changes on the latter. Mucosæ are normal. The Wassermann and Kahn reactions are negative. The section supports the diagnosis of lichen planus atrophicus et annulare, revealing hyperkeratosis, thin short rete-pegs, acanthosis, some separation of the epidermis from the dermis, and fibrotic changes round the skin appendages.

Dr. Parkes Weber: I think the case should be termed one of lichen planus annularis atrophicus, and that one should not omit the word "annularis". The lesion on the penis is absolutely typical, and the site is a common one. The tendencies are I think for the disease to get better any way after a time, especially if the mental condition is satisfactory.

Parapsoriasis—Lichenoid Type.—C. H. WHITTLE, M.D.

A. E. E., aged 54, Dairy farmer. Twelve weeks' history of a papular eruption on the wrists, which spread over the arms, trunk and legs. The onset coincided with an attack of bronchitis, which was preceded by a sore throat.

Family history and previous history, *nil ad rem*.

The eruption consists of bluish-red to brownish-red papules, from a millimetre to 2 centimetres in diameter, with frequently shiny tops and milk-white striæ, resembling lichen planus. They do not itch, however, and there are none to be seen on the mucosæ. They are thickly set on the forearms and thighs and less thickly on the trunk. The larger lesions, chiefly on the trunk, have become complete rings, raised bluish-red with a flat, fawn-coloured centre.

There is a collection of papules on his right shin where the skin is congested and thick and which followed a graze a week or so before the lesions appeared on the wrists. There are some fine delicate rings on the penis. There is no glandular enlargement detectable and he feels well. Wassermann negative.

Every effort will be made to follow the subsequent history of this case.

The lesions have been present for twelve weeks and it is early to say what they are going to do at this stage. Their annular lichen planus-like appearance has persuaded most members to regard the case as lichen planus, in spite of certain points slightly against that diagnosis.

Dr. Brian Russell: I think Dr. Whittle's case might be lichen planus.

The Chairman: I certainly thought it was an annular lichen planus.

POSTSCRIPT (30.8.46).—He states that the eruption has now almost disappeared, there being only a few spots left on the hips, and no fresh spots have appeared. The treatment given was liq. arsenicalis minimis 5 to 8 t.d.s. for three months. The diagnosis of lichen planus is the more likely.—C. H. W.

[April 26, 1946]

Multiple Achalasia, Vertebral Defects and Retarded Growth.—JOHN APLEY, M.D., M.R.C.P.
(by permission of Professor C. BRUCE PERRY).

F. C., at the age of 6, is a puny edition of his normal younger brother, who is only 3 years old (fig. 1).

There are four salient features in the history, and with each a physical abnormality is associated. Their significance can best be emphasized by considering each of these aspects in turn.

(i) *Development.*—There was some delay in passing the customary milestones of physical development. Now, at the age of 6, though the head is the anticipated size for age, the boy is 4 to 5 in. shorter than the average and is of slight build. His proportions are not, however, typically infantile; as an instance, the height is exceeded by the arm span. X-ray of the wrists indicates that skeletal development is barely within the lowest limit of normality.

Mentally bright, I.Q. normal. Psychiatric examination also shows no significant deviation.

(ii) *Enuresis.*—He has always been incontinent and precipitate of urine. Six months ago he came up to hospital with a bladder distended to the umbilicus, and suffering from overflow incontinence. After spinal anaesthesia up to the level of the fifth dorsal vertebra, the distension slowly receded, but the original incontinence and precipitancy were not appreciably relieved. He passes an average amount of normal urine. Intravenous pyelograph normal. Mr. Wilfrid Adams considered the dysfunction was in the nature of an achalasia.

(iii) *Encopresis.*—Though the patient has always been constipated, he has no control over defaecation. He suffers from attacks of abdominal pain and distension, and at these times the constipation is extremely marked. *Barium enema.*—Typical megacolon, with dilatation extending down to the anal sphincter. Unfortunately the spinal anaesthetic had no effect on the lower bowel symptoms.

(iv) *Vomiting.*—Occasional vomiting soon after eating, and not associated with discomfort or malaise. At the age of 3 he vomited after every meal for several weeks. Furthermore, he seems unable to eat more than a small amount at any meal. *Barium swallow.*—Stomach and duodenum normal but oesophagus enlarged.

Thus, four abnormal findings were directly suggested by the history. In addition, there is a dimple in the skin over the lower sacrum, and a tuft of hair over the upper

Parapsoriasis.—BRIAN RUSSELL, M.D.

Multiple Achalasia, Vertebral Defects and Retarded Growth.—JOHN APLEY, M.D., M.R.C.P.
(by permission of Professor C. BRUCE PERRY).

F. C., at the age of 6, is a puny edition of his normal younger brother, who is only 3 years old (fig. 1).

There are four salient features in the history, and with each a physical abnormality is associated. Their significance can best be emphasized by considering each of these aspects in turn.

(i) *Development.*—There was some delay in passing the customary milestones of physical development. Now, at the age of 6, though the head is the anticipated size for age, the boy is 4 to 5 in. shorter than the average and is of slight build. His proportions are not, however, typically infantile; as an instance, the height is exceeded by the arm span. X-ray of the wrists indicates that skeletal development is barely within the lowest limit of normality.

Mentally bright, I.Q. normal. Psychiatric examination also shows no significant deviation.

(ii) *Enuresis.*—He has always been incontinent and precipitate of urine. Six months ago he came up to hospital with a bladder distended to the umbilicus, and suffering from overflow incontinence. After spinal anaesthesia up to the level of the fifth dorsal vertebra, the distension slowly receded, but the original incontinence and precipitancy were not appreciably relieved. He passes an average amount of normal urine. Intravenous pyelograph normal. Mr. Wilfrid Adams considered the dysfunction was in the nature of an achalasia.

(iii) *Encopresis.*—Though the patient has always been constipated, he has no control over defaecation. He suffers from attacks of abdominal pain and distension, and at these times the constipation is extremely marked. *Barium enema.*—Typical megacolon, with dilatation extending down to the anal sphincter. Unfortunately the spinal anaesthetic had no effect on the lower bowel symptoms.

(iv) *Vomiting.*—Occasional vomiting soon after eating, and not associated with discomfort or malaise. At the age of 3 he vomited after every meal for several weeks. Furthermore, he seems unable to eat more than a small amount at any meal. *Barium swallow.*—Stomach and duodenum normal but oesophagus enlarged.

Thus, four abnormal findings were directly suggested by the history. In addition, there is a dimple in the skin over the lower sacrum, and a tuft of hair over the upper

dorsal spine (fig. 2). These indications of the possibility of underlying vertebral defects were borne out by tomographic X-rays, which reveal neural arch anomalies at C6 and 7, at L3, 4 and 5, and at S1, 2 and 3 (fig. 3).

FIG. 1.—Contrast between patient, aged 6, and on his left his younger brother, aged 3.

FIG. 2.—To show dimple over lower sacrum and tuft of hair over upper dorsal spine.

FIG. 3.—Neural arch anomalies at L3, 4 and 5, and S1, 2 and 3.

Comment.—The importance of the case lies in the attempted demonstration that hypothalamic dysfunction may be concerned in the pathogenesis of achalasia.

It is well known that, in one individual, two pathologically enlarged viscera may be present simultaneously. Thus, megacolon and mega-oesophagus may occur together (Correia Neto, 1942), and a large bladder is found in an appreciable proportion of cases of megacolon (Adamson and Arid, 1932). The accepted view is that these and similar "mega"-conditions result from achalasia, which is itself produced by autonomic imbalance. Since this imbalance may conceivably originate in any part of the wide territory covered by the autonomic system, it may be possible to localize the primary focus.

In the present case there are two alternative sites to which the additional evidence points. The first is in the spinal cord. Both the bladder and large intestine are innervated from autonomic centres in the upper lumbar and mid-sacral regions. At the approximate levels of these spinal centres there are vertebral defects which may indicate underlying anomalies of the cord. But the correspondence is no more than approximate, and, moreover, the general retardation of growth could hardly be attributed to cord defects. For these reasons, in the search for a single location for the primary disturbance, the lesion must be placed at a higher level in the central nervous system. If this view is correct the vertebral defects are no more than an indication of coincidental developmental errors elsewhere.

As for the second possible site, there is convincing evidence that centres in the cerebral cortex and hypothalamus are concerned in the regulation of autonomic activity. Worster-Drought and Shafar (1940) suggest that developmental defects of these centres might result in corresponding gastro-intestinal anomalies, and the same authors and others (Watts and Uhle, 1936) postulate a central origin for megacolon and related bladder conditions. In the present case any cortical defect can, presumably, be eliminated because of the normal intelligence of the patient. The possibility of a hypothalamic defect remains, however, and this would suffice to explain adequately not only the autonomic imbalance but also, in the light of recent evidence (Riddoch, 1938, and Dott, 1938), the general retardation of growth.

Hypertensive Retinopathy in a girl aged 10 years 11 months.—JAMES ROBERTSON, M.B., B.S. (by courtesy of Dr. R. LIGHTWOOD).

R. J., female. Admitted 2.4.46.

History.—Attacks of nausea and vomiting associated with headaches for the past year, at first occurring every three months but becoming more frequent; occurring weekly at time of admission and lasting about twenty-four hours. Headaches frontal, worse on right side and accompanied by giddiness. Nausea and loss of appetite during attacks, and occasional vomiting. She tires easily and sleeps badly with twitching of limbs. Getting thinner during last two months. Always thirsty and has polyuria, having to pass water two or three times during the night. No pain or burning on micturition.

Past history.—Measles, whooping-cough and chicken-pox. When aged 2 years had rickets with bow legs; these were fractured and reset. Frequent coughs and colds but no history of scarlet fever. Two years ago she injured her vulva by falling on a spike.

Family history.—Parents and two sisters well. An aunt has "blood-pressure".

On examination.—Pale girl with sallow complexion. Average height and intelligence but rather quiet.

Central nervous system.—Fundi show marked hypertensive retinopathy, with swollen oedematous discs. Retinal arteries are narrowed, veins engorged. Some "nipping" of veins. Star-shaped figures at both maculae more marked on right, and many other patches of exudate which are not of typical "cotton-wool" variety. A few scattered small hæmorrhages.

Cardiovascular system.—P. firm and regular. Cardiac impulse $\frac{1}{4}$ in. outside mid-clavicular line. Second apical heart sound slightly accentuated, otherwise sounds are normal. B.P. 240/170.

Urinary system.—Left kidney just palpable, seems small, is not tender. Right kidney not palpable. Urine S.G. 1015, reaction acid; albumin ++; no sugar; deposit shows epithelial cells, pus, hyaline and cellular casts.

Investigations.—3.4.46: Blood urea 39 mg./100 c.c. 11.4.46: Urea concentration test (1) 1.8 grammes, (2) 2.0 grammes, (3) 2.0 grammes, (4) 2.3 grammes % urea. 13.4.46: Bacteriological report of catheter specimen urine: Film—pus cells ++ and a few R.B.C. Cultures—coliforms ++++. 12.4.46: Blood-count: Hb. 100% (14.8 grammes/100 c.c.) Haldane. R.B.C. 4.8 million. C.I. 1.0. Size 7.1 μ . W.B.C. 15,000 (polys. 59%, lymphos. 32%, monos. 9%). 8.4.46: Urography—Right kidney normal, left kidney hydronephrotic probably. 20.4.46: Retrograde pyelography, L. kidney, large pelvis, single calicle pattern. No features suggestive of hydronephrosis.

The child has been given a full course of sulphonamides and at present the urine is sterile.

Since demonstrating the case differential ureteric catheterization showed the following urea concentration tests:

Left kidney: One hour after urea 1.5%; three hours after urea 2.2%. Deposit: R.B.C. and occasional leucocyte. Culture: Few *Staph. albus* and faecal streptococci.

Right kidney: One hour 0.5%. Deposit: R.B.C. only. Culture: Sterile.

Insufficient urine was obtained from the right kidney after one hour for further estimation as the catheter became blocked.

Following this procedure the girl had a prolonged attack of hypertensive encephalopathy lasting five days. Blood-pressure 260+/220, severe headache, vomiting and oliguria.

In view of the history of frequency, presence of pus and *B. coli* in the urine, and hypertension with hypertensive retinopathy, a diagnosis of chronic pyelonephritis with hypertension in a malignant phase was made. Chronic nephritis was considered unlikely because of the good renal function. The vulval injury is a possible ætiological factor.

Treatment.—Investigations have shown that both kidneys were affected. Removal of one or other kidney would therefore be ineffectual. In an attempt to lower the blood-pressure and intercept the vicious circle of malignant hypertension by producing Addison's disease, bilateral adrenalectomy is being performed. It is proposed to remove the whole of the right adrenal and the major portion of the left, leaving a small amount of adrenal tissue for further regeneration.

On 20.5.46 the right adrenal was removed and a right lumbar sympathectomy performed removing the coeliac ganglion, and the greater, lesser and least splanchnic nerves. The right kidney was found to be small, firm, irregularly pitted and scarred. It was decapsulated and a biopsy taken. The patient survived the operation well with no untoward reactions and no lowering of blood-pressure.

Postscript.—On 13.6.46 the second operation was performed. Three-quarters of the left adrenal was removed and left lumbar sympathectomy performed exactly as on the right side; the left kidney appeared normal. It was decapsulated and biopsy taken.

As a prophylactic measure 5 c.c. eucortone were given b.d. starting on the day of

dorsal spine (fig. 2). These indications of the possibility of underlying vertebral defects were borne out by tomographic X-rays, which reveal neural arch anomalies at C6 and 7, at L3, 4 and 5, and at S1, 2 and 3 (fig. 3).

FIG. 1.—Contrast between patient, aged 6, and on his left his younger brother, aged 3.

FIG. 2.—To show dimple over lower sacrum and tuft of hair over upper dorsal spine.

FIG. 3.—Neural arch anomalies at L3, 4 and 5, and S1, 2 and 3.

Comment.—The importance of the case lies in the attempted demonstration that hypothalamic dysfunction may be concerned in the pathogenesis of achalasia.

It is well known that, in one individual, two pathologically enlarged viscera may be present simultaneously. Thus, megacolon and mega-oesophagus may occur together (Correia Neto, 1942), and a large bladder is found in an appreciable proportion of cases of megacolon (Adamson and Arid, 1932). The accepted view is that these and similar "mega"-conditions result from achalasia, which is itself produced by autonomic imbalance. Since this imbalance may conceivably originate in any part of the wide territory covered by the autonomic system, it may be possible to localize the primary focus.

In the present case there are two alternative sites to which the additional evidence points. The first is in the spinal cord. Both the bladder and large intestine are innervated from autonomic centres in the upper lumbar and mid-sacral regions. At the approximate levels of these spinal centres there are vertebral defects which may indicate underlying anomalies of the cord. But the correspondence is no more than approximate, and, moreover, the general retardation of growth could hardly be attributed to cord defects. For these reasons, in the search for a single location for the primary disturbance, the lesion must be placed at a higher level in the central nervous system. If this view is correct the vertebral defects are no more than an indication of coincidental developmental errors elsewhere.

As for the second possible site, there is convincing evidence that centres in the cerebral cortex and hypothalamus are concerned in the regulation of autonomic activity. Worster-Drought and Shafar (1940) suggest that developmental defects of these centres might result in corresponding gastro-intestinal anomalies, and the same authors and others (Watts and Uhle, 1936) postulate a central origin for megacolon and related bladder conditions. In the present case any cortical defect can, presumably, be eliminated because of the normal intelligence of the patient. The possibility of a hypothalamic defect remains, however, and this would suffice to explain adequately not only the autonomic imbalance but also, in the light of recent evidence (Riddoch, 1938, and Dott, 1938), the general retardation of growth.

The hands: In both hands there is complete fusion of the soft tissues of all digits forming a solid conical mass. This mass is fixed to the proximal part of the hand in a position of semiflexion, there is no movement present in the metacarpophalangeal joint region or in the mass itself. A shallow groove serves to demarcate the thumb, which is fused in the position of opposition, and a second groove demarcates the distal portion of the ulnar digit. The nails are fused into a continuous band across the mass, this band being deeply grooved in the positions already noted. Wrist-joints and other parts of the upper extremities are normal.

The feet: All digits on both feet are fused. There is no definite groove demarcating the great toe, but there is club-shaped thickening representing the great toes. There is a continuous nail band as in the hands. There are no movable joints between phalanges and metatarsals (figs. 1, 2, 3).

FIG. 1.

FIG. 2.

FIG. 3

Acrocephaly-Syndactyly.

X-ray appearances.—Skull: The base of the skull is very short antero-posteriorly. The pituitary fossa is shallow, there is marked increase in size of the greater wings of the sphenoid. The orbital plates of the frontal are short. The petrous bone is small and on a lower level than normal. A fissure is visible between the basi-occipital and basisphenoid bones. The height of the vault is greater than normal, $\frac{3}{4}$ in. greater than control. There is extreme thinning of the bone with linear striations in the frontal and parietal regions and disappearance of the inner table. In the occipital region the thickness of the skull is almost normal but there are "digital impressions". The coronal suture is not visible, and the lambdoid suture is poorly defined.

Hands: In both hands five normal metacarpals are present. The phalanges are represented by irregular masses of bone which are fused to each other. Five of these bony masses can be identified in the right hand and six in the left.

Feet: In each foot the three outer metatarsals appear normal but the inner two are fused, the first metatarsal being very short and branching off the second about one-third of its length from the proximal end. In the right foot there are three small distal bones on the outer side, and three irregular shaped proximal bony masses representing the phalanges, to the third of these is attached another irregular bone which represents the proximal phalanx of the second toe, but there is no corresponding distal phalanx. The phalanges of the great toe are represented by a fused mass of bone. In the left foot there are three small bones representing the three outer distal phalanges. The proximal phalanges are represented by three bony masses, each of which suggests fusion of several small bones and corresponds less to the metatarsal arrangement than in the right foot.

GREIG, D. M. (1926) *Edinb. med. J.*, N.S., 33, 189.

the second operation. On the fourth day after operation, the girl had a puffy face and there was a good deal of water retention. The eucortone was discontinued and the œdema vanished.

After operation, the blood-pressure fell immediately to 100/60, rising slowly during the next four days to 184/160. At this point the eucortone was discontinued. During the next fortnight the blood-pressure gradually fell to 134/100. On July 1 there was a small rise to 160/120 and an immediate fall to 140/110 where it remained.

The child was seen again on 16.9.46. Blood-pressure 160/120. Urine sterile. No albumin or deposit. She was very well and gaining weight, and completely symptom-free since the operation. Fundi: Discs clear, no papilloedema. The exudates remain but are smaller, whiter and sharply defined. No hæmorrhages or nipping of veins.

Biopsy results.—Right kidney shows some periglomerular fibrosis. The glomeruli are a little reduced in size though a rather large one is present. On the whole there are only a few ischæmic changes.

Left kidney shows marked thickening of small arteries. Scanty sclerosed glomeruli with areas of interstitial fibrosis and tubular atrophy.

Right suprarenal normal. Left suprarenal shows large amount of cortical lipid. Arteries thickened.

Exophthalmic Goitre in a Child Aged 11 Years.—W. R. MAY, M.R.C.S., L.R.C.P. (by courtesy of Dr. REGINALD LIGHTWOOD).

J. M., aged 11 years 6 months. No family history of thyroid disease.

Personal.—Resident in London except during war years (one year in Wales, eight months in Hayes (Middlesex), and two years in Reading).

Present illness.—Admitted St. Mary's Hospital April 9. For two years mother has noticed she has been restless and excitable. For six months she has complained of headaches and mother noticed "staring". Fullness of the throat for one month and increased sweating and appetite.

On examination.—Height 4 ft. 9 in. Weight 5 st. 6 lb. Restless and thin. Obvious exophthalmos right more than left. Diffuse enlargement of thyroid gland. Neck measurement $11\frac{1}{4}$ in. Sexual development—breasts undeveloped; no pubic hair. Slight slow tremor of fingers and tongue. Blood-pressure 150/70. Urine—sugar trace. Blood-count: Hb. 105% (Haldane). Size 7.0 μ . W.B.C. 7,500 (polys. 62%, lymphos. 30%, monos. 8%).

Treatment commenced with methyl thiouracil 0.1 gramme daily increasing to 0.1 gramme three times daily. No toxic manifestations observed to date.

Acrocephaly-Syndactyly.—BERYL D. CORNER, M.D.

This case shows a severe degree of almost symmetrical syndactyly of hands and feet associated with gross abnormality of the skull, it has therefore been entitled acrocephaly-syndactyly as it is a typical example of Apert's syndrome. The condition of the skull would appear to fall into the group of cases described by Greig (1926) as true oxycephaly.

M. C., female, aged 6 months. First child, born after normal pregnancy by Caesarian section owing to failure of engagement of the head in the pelvis. Mother aged 41 years, father 43 years. Birth-weight $7\frac{1}{2}$ lb. Abnormality of head and extremities noticed at birth.

No family history of congenital abnormalities.

Examination.—The child is healthy and of normal size for her age. Sight and hearing appear normal, and mental development seems average.

The head: Appearance of the head is markedly brachycephalic with flat occipital region and shortened antero-posterior diameter. The height of the skull is much increased, maximum being just behind the anterior fontanelle. The orbits are shallow and separated by an abnormally broad depressed bridge of the nose, they slope downwards and outwards. Supra-orbital ridges are poorly defined, and above them is a deep groove passing across the whole forehead. The upper part of the frontal bone shows marked forward bulging which overhangs the face. The metopic suture is open to the glabella, and the anterior fontanelle is situated far forward. The posterior fontanelle is closed and no other sutures can be palpated. The superior maxillæ are small and depressed, the nose is short and there has been partial nasal obstruction with snuffles since birth. There is bilateral exophthalmos with divergent strabismus, but no evidence of optic atrophy or abnormality of the retina. Owing to the short mouth, the tongue protrudes continuously. The lower jaw protrudes slightly and appears large in comparison with the rest of the face.

Head measurements: Circumference $16\frac{1}{2}$ in. External auditory meatus to highest point of skull 7 in. Glabella to highest point $4\frac{1}{4}$ in.

The hands: In both hands there is complete fusion of the soft tissues of all digits forming a solid conical mass. This mass is fixed to the proximal part of the hand in a position of semiflexion, there is no movement present in the metacarpophalangeal joint region or in the mass itself. A shallow groove serves to demarcate the thumb, which is fused in the position of opposition, and a second groove demarcates the distal portion of the ulnar digit. The nails are fused into a continuous band across the mass, this band being deeply grooved in the positions already noted. Wrist-joints and other parts of the upper extremities are normal.

The feet: All digits on both feet are fused. There is no definite groove demarcating the great toe, but there is club-shaped thickening representing the great toes. There is a continuous nail band as in the hands. There are no movable joints between phalanges and metatarsals (figs. 1, 2, 3).

FIG. 1.

FIG. 2.

FIG. 3

Acrocephaly-Syndactyly.

X-ray appearances.—Skull: The base of the skull is very short antero-posteriorly. The pituitary fossa is shallow, there is marked increase in size of the greater wings of the sphenoid. The orbital plates of the frontal are short. The petrous bone is small and on a lower level than normal. A fissure is visible between the basi-occipital and basisphenoid bones. The height of the vault is greater than normal, $\frac{3}{4}$ in. greater than control. There is extreme thinning of the bone with linear striations in the frontal and parietal regions and disappearance of the inner table. In the occipital region the thickness of the skull is almost normal but there are "digital impressions". The coronal suture is not visible, and the lambdoid suture is poorly defined.

Primary Hyperplasia of the Parathyroids in a Boy Aged 8 Years.—R. J. PUGH, M.B., M.R.C.P. (for W. G. WYLLIE, M.D., F.R.C.P.).

The patient was under observation in hospital for a period of five months prior to diagnosis, and gave a history for three months preceding admission, before which he had been in good health. An insidious onset of anorexia, increasing polydipsia with enuresis, occasional vomits and frequent pains in the head, abdomen and behind the knees, was reported. There was progressive muscular weakness so that the patient was no longer able to walk, and had to pull himself to his feet. Previously there had been an attack of tonsillitis at the onset, but the only other illness was measles. The parents and two siblings were healthy.

Apart from extreme lethargy and evidence of recent weight loss, no significant findings were made on examination, but subsequently he frequently exhibited nuchal stiffness and frontal headache.

FIG. 1.—Radiograph of patient's arm (R) with control of the same age (L). (Exposure on the same plate.)

FIG. 2.—Micrograph showing pseudo-alveoli and giant nuclei. $\times 147$.

Initial findings.—Blood-count: R.B.C. 5,280,000; Hb. 85%; C.I. 0.81. W.B.C. 8,900 (50% polymorphs). B.S.R.: 47 mm. in one hour. C.S.F.: No abnormal findings; pressure 70 mm. Urine: Acid; alb. 15 mg.%; no deposit; sterile; sugar absent. Blood urea: 33 mg.%.
X-rays: Nothing abnormal.

1:1000 Mantoux: Very strongly positive. B.P. 95/65.

Course in hospital.—During the next five months the symptoms continued unabated; the fluid intake averaged 55 oz. daily, while the intermittent bouts of vague pains increased in severity sometimes with tenderness of the limbs and back on turning in bed for washing. Anorexia and ready fatigue were extreme. No evidence of active tuberculosis could be found radiologically or in gastric washings. There was no benefit from posterior pituitary extract injection. The blood urea remained normal. Intravenous pyelography was attempted on three occasions, but renal concentration was lacking. Routine agglutination reactions were uniformly negative. The erythrocyte sedimentation tube remained around 60 mm. in one hour.

The possibility of a tuberculoma in the floor of the fourth ventricle was considered, and a normal ventriculogram was performed by Mr. Wylie McKissock.

Attention was drawn to the skeletal system by the appearance of rarefaction in the necks of the femurs, and by the necrotic nature of the cranial burrholes. Histology of

the skull showed extreme osteoporosis. Urine gave a heavy precipitate with Sulkowitch reagent.

Blood chemistry.—Serum calcium 18.8 mg.%; inorganic blood phosphorus 2.8 mg.%; alkaline serum phosphatase 93 units.

Operation.—An exploration of the parathyroids was undertaken by Mr. Charles Donald, and revealed a tumour the size of a large hazelnut, purple in colour, inferior to the thyroid capsule beneath the sternal notch. This was removed. (Histological report in detail, see addendum.)

Progress.—There was immediate amelioration of many symptoms, including anorexia, pain in movements of limbs, headache, and neck stiffness. The fluid intake dropped to 25 oz. daily, and there has been no further enuresis. The alkaline serum phosphatase continued greatly raised (107 and 87 units respectively). The blood calcium fell more slowly over the course of forty-eight hours, to 8.9 mg.%, and in six days was down to 6.5 mg.%. There was no tetany, and the level was restored by high calcium intake with the addition of 10,000 units of vitamin D daily. There has been a gain in weight of over 4 lb. in less than three weeks, with improvement in muscle tone. The B.S.R. remained raised and was 61 mm. in one hour three weeks after operation, when the blood chemistry revealed: Serum calcium 9.4 mg.%; inorganic blood phosphorus 3.3 mg.%; alkaline serum phosphatase 62 units.

Progress satisfactory. We are indebted to Dr. W. W. Payne for the biochemical investigations, and to Dr. Martin Bodian for the histological examination.

ADDENDUM

Histological report.—Predominant cell type of transitional principal variety with few isolated oxyphil cells. Between them many giant nuclei are present as well as few cells with multiple nuclei and mitotic figures. Oedema, congestion and frank hæmorrhages lead to breaking up of cell columns and to formation of "pseudo-alveoli". Much droplet glycogen is present in the cells. There is no evidence of neoplastic growth. The findings indicate hyperplasia of the parathyroids.

Tumour of the Optic Chiasm and Nerve Sheaths in a Girl Aged 2 years 9 months, Showing Some Manifestations of Neurofibromatosis.—R. J. PUGH, M.B., M.R.C.P. (for BERNARD SCHLESINGER, M.D., F.R.C.P.).

Patient has exhibited progressive proptosis of the left eye for the last five months, with increasing impairment of vision, difficulties in feeding, and weight loss. For the last month there have been frequent transient left frontal head pains with hyperparæsthesia over the left trochlear region. There was no history of vomiting, or other neurological symptoms.

Her father shows patches of café-au-lait pigmentation about the trunk, and a single molluscum in the neck.

Examination revealed a wasted child weighing only 22 lb., with many café-au-lait patches on the trunk, and a soft nodule on the scalp. The left eye is markedly proptosed, the right slightly so. Optic fundi show advanced atrophy on the right while the left is of normal colour and vascularization, but is displaced forwards about 6 dioptries.

FIG. 1.—Radiograph showing flattening of pituitary fossa with erosion of anterior clinoid processes.

FIG. 2.—Enlarged right optic foramen (indicated by arrow).

Stereoscopic skull X-rays reveal thickening of the greater wing of the sphenoid with erosion of the anterior clinoid processes, and gross widening of both optic foramina to about three times normal size for age.

Cerebrospinal fluid examination gave a pressure of 95 mm., a protein content of 90 mg.%, cells absent, sugar 65 mg.% and chlorides 740 mg.%. Wassermann reaction of the blood and C.S.F. was negative. Mantoux: 1:1000 negative.

Biopsy of lump in subcutaneous tissues of scalp was reported as having the histological appearance of a soft fibroblast undergoing mucoïd degeneration (Dr. Martin Bodian).

Discussion.—The case resembles those described by Cushing (1923), and Wyllie (1924) of glioma of the optic chiasm invading the nerve sheaths; of the former's 18 cases, 6 showed evidence of generalized neurofibromatosis, while Davies (1940) has found in the literature since 1870, 38 cases of glioma of the optic chiasm in association with neurofibromatosis, in 12 of which there was an hereditary element.

Familial Hæmolytic Anæmia.—CHARLES PINCKNEY, F.R.C.P.

D. R., male, aged 6 months. Sent to hospital with history of bronchitis and pallor since birth, which has increased recently. A first baby, birth-weight 7 lb. 10 oz., normal labour, not breast-fed. Taking well till previous week when developed bronchitis.

Father had splenectomy; report on grandfather as having had splenectomy.

On examination.—Marked pallor, signs of generalized bronchitis, spleen enlarged and firm, half-way to umbilicus.

12.3.46: Admitted to hospital. Investigations: Hb. 35%, reticulocytes 30%. Fragility test—commencing hæmolysis in 0.72% saline. Blood transfusion given: Hb. raised to 100%.

Discharged well but spleen still enlarged.

Seen again in Out-patients, 23.4.46; weight gain satisfactory, but increase of anæmia present. Investigation showed R.B.C. 2,350,000; Hb. 40%; reticulocytes 1%. Admitted for further transfusion and splenectomy.
